Gastrointestinal tract and rheumatic disease

■ MATILDA HAGAN ■ RAYMOND CROSS

- Joint disease is a common complication of gastrointestinal diseases. The exact pathogenesis of these disorders is unclear.
- The arthritides associated with gastrointestinal disorders can be highly variable, including axial, peripheral, pauciarticular, or polyarticular arthritis.
- Inflammatory bowel diseases, particularly Crohn disease and ulcerative colitis, are often complicated by the development of peripheral or axial arthritis.
- Arthritides associated with gastrointestinal infections are often self-limited and rarely result in chronic symptoms.
- Treatment of the underlying gastrointestinal disorder often results in resolution of the associated arthritis.

INTRODUCTION

Gastrointestinal illnesses are associated with extraintestinal manifestations of disease. It is not known why extraintestinal complications of disease occur; however, since many of these complications are seen in patients with active gastrointestinal inflammation, it has been postulated that increased intestinal permeability resulting from the underlying inflammatory process allows luminal antigens to be presented to the systemic immune system. Alternatively, because many inflammatory gastrointestinal illnesses cause a systemic inflammatory response, it is possible that the joint and other sites are innocent bystanders in the inflammatory process. Recent evidence has linked adhesion molecules, vascular adhesion protein-1, and T cells bearing β_7 integrin to joint synovial fluid,¹ which provides a direct link between intestinal and joint inflammation. Gastrointestinal diseases that have been linked to inflammatory arthritis include but are not limited to inflammatory bowel disease (comprised of ulcerative colitis and Crohn disease), celiac disease, bacterial enteritis, Whipple disease, vasculitides affecting the gastrointestinal tract such as polyarteritis nodosa, Henoch-Schönlein purpura, Behçet syndrome, and microscopic colitis.

INFLAMMATORY BOWEL DISEASE: CROHN DISEASE AND ULCERATIVE COLITIS

Inflammatory bowel disease (IBD), consisting of ulcerative colitis (UC) and Crohn disease (CD), is a chronic inflammatory condition of the intestines typically affecting young adults. The cause of IBD is unknown. However, a combination of a genetic predisposition, dysregulated immune system, and environmental antigens play a role in the development of IBD. CD and UC are usually easily distinguished from each other by clinical symptoms, endoscopic findings, and histologic characteristics. However, in approximately 15% of cases, differentiation between CD and UC is difficult. These patients are classified as having IBD type undetermined or indeterminate colitis. The extraintestinal manifestations, treatment options, and prognoses differ by disease.

UC usually presents with bloody diarrhea. UC is seen more often in nonsmokers and former smokers than in active smokers. The onset of bloody diarrhea after a patient has quit smoking is consistent with the diagnosis of UC until proven otherwise. The extent of colonic involvement determines the UC patient phenotype. UC phenotype is typically broken down into three groups: inflammation limited to the rectum (ulcerative proctitis), inflammation limited to the left colon (left-sided colitis), and

inflammation proximal to the splenic flexure (extensive colitis or pancolitis). The amount of colonic involvement is important, because patients with pancolitis are more likely to be treated with steroids, become hospitalized for UC, undergo colectomy, and develop colorectal cancer.^{2,3} Patients with UC have disease limited to the colon only; endoscopic examination reveals inflammation beginning at the anal verge and extending proximally in a continuous fashion. The inflammatory process tends to be more superficial in UC than in CD. Decreased anatomic markings, friability, and erosions are endoscopic hallmarks of the disease (Fig. 37.1). Patients with severe disease can have large or confluent ulcerations that make differentiation from CD difficult. Small bowel involvement does not occur except in patients with pancolitis who have “backwash ileitis” (inflammation in the distal 5 cm of terminal ileum). Skip lesions should not be seen; however, once patients undergo medical therapy, the inflammation can appear patchy. Biopsy specimens typically reveal both acute and chronic inflammation; active colitis is defined by the presence of neutrophils in the crypts (cryptitis and crypt abscess), whereas chronicity is established by expansion of the basal surface with plasma cells and lymphocytes, with distortion of the architecture (Fig. 37.2).

CD can affect any location in the gastrointestinal tract from the mouth to the anus. The terminal ileum is the most commonly affected site. CD is distinguished from UC by the presence of small bowel involvement, development of strictures and/or fistulas, endoscopic appearance, and histopathologic findings (Table 37.1). Symptoms of CD are heterogeneous and depend on the patient's phenotype.⁴ Patients with *inflammatory* CD usually have nonbloody diarrhea and crampy lower abdominal pain. Systemic symptoms may or may not be present. Patients with *obstructing* CD usually have intermittent abdominal pain, bloating, borborygmi, and obstipation. The symptoms are usually exacerbated by eating. Nausea and emesis can be seen as the strictures become more severe. The diarrhea associated with obstructive CD usually occurs after an episode of pain and is associated with relief of symptoms (post-obstructive diarrhea). Patients with *penetrating* CD have fistulas from a segment of bowel to adjacent organs or to another loop of intestine. Sinus tracts or severe transmural inflammation can result in intraabdominal abscess formation. Some 20% to 40% of patients develop perianal fistulas with or without abscess.⁵⁻⁷ This complication results in perianal pain and drainage from the fistula sites. Fistulas coupled with abscess are often associated with severe pain and systemic symptoms. The endoscopic appearance of the bowel in CD usually allows it to be easily distinguished from UC. Rectal involvement is less common, and patients typically have skip lesions with areas of normal intervening mucosa. The ulcerations seen in CD are typically large and deep and can be serpiginous (Fig. 37.3). The earliest lesions in CD are aphthous ulcers similar to those seen in the oral mucosa. On histopathologic examination, an acute and chronic inflammatory process is seen as in patients with UC; however, surgical specimens can reveal transmural inflammation and transmural lymphoid aggregates. Mucosal biopsy samples reveal pathognomonic noncaseating granulomas in 30% to 50% of patients (Fig. 37.4).⁸ Small bowel imaging can demonstrate ulcerations, stricture, or fistula in the small bowel.

Extraintestinal manifestations of inflammatory bowel disease

Extraintestinal manifestations associated with CD and UC are common, occurring in 20% to 30% of patients.^{7,9} Although joint manifestations are the most frequent,¹⁰ the oral cavity, eyes, skin, bone, kidneys, and biliary tract can also be involved. The incidence of extraintestinal manifestations differs for CD and UC, and the presentation of extraintestinal symptoms varies depending on onset, site, and activity of the bowel disease. With regard to extent of the disease, widespread bowel involvement is associated

with greater odds of developing extraintestinal manifestations than more limited bowel disease. Patients with extensive UC experience extraintestinal manifestations 22% of the time, whereas patients with left-sided colitis and proctitis have extraintestinal symptoms 12% and 5% of the time, respectively.¹¹ Likewise, patients with ileocolonic CD have extraintestinal manifestations 37% of the time compared with 25% of the time in patients with isolated ileal disease.¹² Some extraintestinal manifestations such as large joint monoarticular arthritis tend to occur when the bowel disease is active, whereas others such as small joint symmetrical arthritis occur before diagnosis or when the disease is quiescent. Some trends in gender differences and age at presentation are seen for certain extraintestinal manifestations. Women are more likely to have erythema nodosum and ocular manifestations, whereas men are more likely to have primary sclerosing cholangitis and ankylosing spondylitis¹³ (Table 37.2).

Fig. 37.1 Endoscopic view of a section of colon in a patient with ulcerative colitis. The entire visualized mucosa is affected in a continuous fashion with loss of the normal vascular markings and light reflex. The mucosa is erythematous, friable, and ulcerated.

Fig. 37.2 Section of colon showing classic features of active chronic disease, including marked architectural distortion (crypt branching, crypt atrophy, crypt dropout) as well as expansion of the lamina propria by lymphoplasmacytic infiltrate and focal crypt abscesses (40x). (Courtesy Harris Yfantis, MD.)

Peripheral arthritis associated with inflammatory bowel disease

Peripheral arthritis, both polyarticular and pauciarticular, is estimated to occur in 10% to 20% of patients with IBD, with a higher prevalence of peripheral arthritis in CD than in UC.^{16,17} Recent studies have suggested several causes of IBD-associated peripheral arthritis. HLA-DR103 and HLA-B*27 have been associated with pauciarticular arthritis and HLA-B44 has been associated with polyarticular arthritis. Increased gut permeability to bacterial antigens may result in the induction of articular symptoms, primarily pauciarticular arthritis.¹⁷ IBD-related peripheral arthritis is diagnosed clinically, since radiographic findings often are normal and show no signs of joint erosion or deformity. Pauciarticular arthritis is more common than polyarticular arthritis in IBD.¹⁷ Men and women are affected equally. Pauciarticular arthritis, also known as *type I arthropathy*, involves four or fewer joints and tends to be acute and self-limited, commonly affecting large joints such as the knees, wrists, and ankles. Its presentation coincides with active disease, and it often emerges upon relapses of IBD. The duration

Fig. 37.3 Endoscopic view of the ileum in a patient with Crohn disease. Deep linear and serpiginous ulcers with intervening edematous mucosa are present (cobblestoning).

TABLE 37.1

Crohn disease and ulcerative colitis

	Symptoms/characteristics	Gastrointestinal involvement	Endoscopic findings	Pathologic features
Crohn disease	Abdominal pain, nonbloody diarrhea, perianal and internal fistulas Active smoking influences disease	Can involve intestine from mouth to anus	Skip lesions, serpiginous or deep ulcerations, strictures, fistulas, small bowel involvement	Transmural inflammation, noncaseating granulomas, skip lesions
Ulcerative colitis	Bloody diarrhea, tenesmus More common in nonsmokers and former smokers	Involves colon only	Superficial erosions or smaller ulcerations, continuous involvement from rectum to proximal colon	Continuous histologic inflammation from rectum to proximal colon

TABLE 37.2

Extraintestinal manifestations of disease in patients with inflammatory bowel disease

Manifestation	Description	Epidemiology	Correlation with active bowel disease	Treatment
Erythema nodosum	Painful, tender, raised, red nodules, often found on the anterior lower legs	1%-9% UC 6%-15% CD 5:1 female-male	90% associated with active bowel disease	Resolves with treatment of active bowel disease
Pyoderma gangrenosum	Ulcers on lower limbs, trunk, and adjacent to surgical stomas	0.5%-2% IBD	Not associated with active bowel disease ⁸	Immunosuppressive therapy; occasionally shows spontaneous resolution
Aphthous ulcers	Oral ulcerations in buccal mucosa	20%-30% CD	Associated with active bowel disease Associated with ocular and articular symptoms	Resolve with treatment of active bowel disease ¹²
Uveitis	Eye pain, redness, loss of visual acuity, floaters	3:1 female-male ¹⁵	Anterior uveitis: 30% associated with erythema nodosum Posterior uveitis: 90% associated with arthritis, particularly ankylosing spondylitis ¹⁵	Topical corticosteroids; systemic immune suppressants for severe cases
Episcleritis	Eye redness, irritation, and watering	5%-8% IBD 3:1 female-male	Associated with active bowel disease	Resolves with treatment of active bowel disease or topical corticosteroid therapy
Primary sclerosing cholangitis	Recurrent biliary sepsis, abdominal pain, pruritus, complications of portal hypertension and end-stage liver disease	3%-5% UC ¹³ Male preponderance	Not associated with active bowel symptoms; associated with colorectal cancer	Supportive therapy, management of complications of disease

CD, Crohn disease; IBD, inflammatory bowel disease; UC, ulcerative colitis.
Additional data from Reference 14.

of arthritis can be up to 10 weeks, with a mean of 5 weeks; however, 10% to 20% of patients with pauciarticular arthritis will develop persistent joint symptoms. Pauciarticular arthritis is associated with an increased risk of other extraintestinal manifestations such as erythema nodosum and uveitis (see Table 37.1).

Polyarticular arthritis, also known as *type II arthropathy*, involves five or more joints and commonly affects the small joints in the hand, particularly the metacarpophalangeal joints.¹⁷ Its presentation is independent from the activity of the disease.¹⁸ In fact, polyarticular arthritis can occur before the diagnosis of IBD. The presentation can be insidious with symptoms lasting for years, with a mean duration of 3 years. Polyarticular arthritis is associated with uveitis (see Table 37.1).

Axial arthritis associated with inflammatory bowel disease

Sacroiliitis occurs in 4% to 32% of patients with IBD.^{16,19} The varying incidences can be explained by differences in whether the diagnosis is made based on clinical symptoms, plain radiographs, or cross-sectional CT images (Fig. 37.5). Patients typically have stiffness and/or pain in the buttocks that is worse in the morning or after rest. The symptoms commonly improve with exercise. Initial plain radiographs show unilateral or bilateral iliac erosion, followed by fusion of the sacroiliac joint from chronic inflammation. Sacroiliitis occurs more commonly in patients with CD than in patients with UC.²⁰ Patients with CD-related sacroiliitis are more likely to develop peripheral arthritis.²¹

IBD-associated ankylosing spondylitis manifests identically to idiopathic ankylosing spondylitis and is estimated to occur in 4% to 10% of IBD patients.^{22,23} A higher prevalence of 6% is seen in patients with CD compared with 2.6% in patients with UC.²⁴ However, it has been theorized that this number would be larger if all patients with ankylosing spondylitis were assessed for IBD.²⁵ One study found a 55% prevalence rate of any IBD-associated serologic marker, such as perinuclear antineutrophil cytoplasmic antibody (p-ANCA), antibodies to the cell wall mannan of *Saccharomyces cerevisiae* (ASCA), or antibodies to porin protein C of *Escherichia coli* (OmpC), in patients with ankylosing spondylitis who had no clinical signs or symptoms of IBD. It has been suggested that detection of p-ANCA in patients with ankylosing spondylitis should be an indicator for further evaluation given the high frequency of p-ANCA in patients with ankylosing spondylitis who also have UC.²⁶ Males and females are equally affected.

IBD-related ankylosing spondylitis has a strong genetic component, with a high correlation with the HLA-B27 antigen. More recently, CD and ankylosing spondylitis have been associated with interleukin 23 receptor variants

Fig. 37.5 Frontal radiograph of the lumbar spine shows fine bridging bone (syndesmophytes) across the intervertebral disk space (short black arrows) as well as ossification of the posterior interspinous ligaments (long black arrow). This results in a bamboo spine, which predisposes to spinal fractures (white arrow). The sacroiliac joints are fused. (Courtesy Jade Wong, MD.)

and the major histocompatibility complex.²⁷⁻²⁹ Symptoms of ankylosing spondylitis may include thoracic or lumbar pain, alternating buttock pain or chest pain, and morning stiffness of the spine and thorax. The spinal vertebrae of the lumbar, thoracic, and cervical regions may fuse, forming a so-called bamboo spine that limits mobility, causes changes in posture, and

TABLE 37.3

Organisms associated with reactive arthritis

<i>Campylobacter jejuni</i>	<i>Clostridium difficile</i>
<i>Yersinia enterocolitica</i>	<i>Chlamydia trachomatis</i>
<i>Yersinia pseudotuberculosis</i>	<i>Salmonella typhimurium</i>
<i>Shigella flexneri</i>	<i>Salmonella enteritidis</i>
<i>Shigella dysenteriae</i>	

leads to a loss of flexibility. The spine can easily fracture in response to minor trauma (see Fig. 37.5). Radiographically, formation of characteristic syndesmophytes between the vertebral bodies is seen, as the annulus fibrosis gradually ossifies. Axial arthritic symptoms manifest several years before active IBD is detected, and the arthritic disorder is considered independent in its disease course from the underlying bowel disease.

Arthralgias without frank arthritis occur in 14% of CD patients compared with 5% of UC patients.¹⁵ Polyarticular involvement is more prevalent than monoarticular or oligoarticular involvement.²⁷ Arthralgias can affect any joint, and their presentation coincides with active disease and emerges upon relapses of IBD. The only exception is in the case of arthralgias associated with steroid withdrawal (pseudorheumatism or steroid withdrawal syndrome). In this clinical situation, joint pain coincides with steroid withdrawal, requiring escalation of the corticosteroid dosage.

BACTERIAL ENTERITIS

Bacterial enteritis refers to infection and inflammation of the intestines caused by infection with a variety of bacterial pathogens, including *Campylobacter jejuni*, *Clostridium difficile*, *Yersinia enterocolitica*, *Yersinia pseudotuberculosis*, *Shigella*, and *Salmonella* (Table 37.3). Symptoms related to bacterial enteritides usually present acutely and include nonbloody or bloody diarrhea, abdominal cramping, and systemic symptoms. Patient history is important in determining the causative bacteria. Benefits of empiric antibiotic treatment are dubious in healthy adults; further, antibacterial treatment can precipitate hemolytic-uremic syndrome in patients with enterohemorrhagic *E. coli* infection.

Approximately a quarter to a third of patients with bacterial enteritis develop reactive arthritis,³⁰ usually within a few days to a few weeks after infection.³¹ In the majority of patients, the arthritis involves multiple large joints and is migratory. The arthritis tends to be asymmetric and usually affects the lower extremities more than the upper extremities. In addition, patients can develop an enthesitis or sacroiliitis. The arthritis is usually self-limiting, lasting a week to several months³²; however a chronic, relapsing arthritis occurs in a minority of patients.³³ The presence of HLA-B27 is associated with an increased likelihood of developing reactive arthritis, an increase in its severity, and likelihood of chronicity.²⁶ Additionally, a *Y. pseudotuberculosis* O:3 infection is associated with increased risk of arthritis.^{34,35} Treatment of the underlying bacterial enteritis with antibiotics does not hasten resolution of the joint symptoms.^{36,37}

CELIAC DISEASE

Celiac disease is a chronic inflammatory condition of the proximal small intestine resulting from exposure to gluten in a genetically predisposed host. It is perhaps the only autoimmune disease in which the environmental precipitant is known.³⁸ Celiac disease occurs primarily in whites of Northern European descent, with a prevalence in North America of 1 in every 133 people.³⁹ However, the prevalence may be underestimated, because a significant proportion of patients are either undiagnosed or asymptomatic. Two times more adult women than men are affected, but the difference diminishes after age 65.⁴⁰ The disease is associated with HLA class II alleles DQA1*0501 and DQB1*0201.⁴¹ Ingestion of gluten, a storage protein in wheat, and similar proteins in barley and rye leads to an inappropriate T cell–mediated inflammatory response through activation of both the innate and adaptive immune systems, causing damage to the small intestine and eventual destruction of the intestinal villi. Destruction of the villi results in a malabsorption syndrome. Symptoms of celiac disease include chronic nonbloody diarrhea, weight loss, abdominal bloating and distention, and overall failure to thrive.⁴² In adults, the presentation can be more protean. The most common clinical presentation in adults is iron-deficiency anemia.⁴³

Fig. 37.6 Duodenal mucosa showing marked villous blunting and crypt elongation. There is intraepithelial lymphocytosis, and the lamina propria is expanded by increased numbers of lymphocytes and plasma cells (4×). (Courtesy William Twaddell, MD.)

Celiac disease is diagnosed by biopsy of the small intestine, which reveals increased lymphocytes, crypt hyperplasia, and varying degrees of villous atrophy (Fig. 37.6). The treatment for celiac disease is a gluten-free diet, which almost always leads to resolution of symptoms. Celiac disease is associated with a variety of extraintestinal manifestations, including aphthous ulcers, dermatitis herpetiformis, and development of reactive arthritides.⁴⁴

Celiac disease–associated arthritis can be peripheral, axial, or both⁴⁵ and commonly affects the lumbar spine, hips, and knees.⁴⁶ The joint symptoms often precede the diagnosis of celiac disease. Treatment with a gluten-free diet not only improves the intestinal symptoms and anemia but has been shown to decrease the duration of joint symptoms resulting in resolution of the arthritis within 6 months.⁴⁶

WHIPPLE DISEASE

Whipple disease is a rare, chronic systemic infection caused by the actinomycete *Tropheryma whippelii*. Approximately 12 new cases are diagnosed annually around the world,⁴⁷ occurring predominantly in white males between 40 and 60 years of age.⁴⁸ *T. whippelii* is thought to cause chronic infection by evading the immune system. Similarly, there may be a correlation between Whipple disease and defective ability of the host to clear the bacteria.^{48,49} Patients with Whipple disease typically have diarrhea secondary to fat malabsorption (steatorrhea), weight loss, fever of unknown origin, and arthritis. Neurologic symptoms are present in a minority of cases. Whipple disease is diagnosed by biopsy of the small intestinal mucosa, which reveals lymphatic dilation with macrophages that stain positive with periodic acid–Schiff stain and contain gram-positive, non-acid-fast bacilli in the lamina propria. Whipple disease is treated successfully with long-term administration of antibiotics, such as an initial 2-week course of an intravenous antibiotic like ceftriaxone or meropenem followed by at least a 1-year course of an oral antibiotic such as trimethoprim/sulfamethoxazole.⁵⁰ Relapses are common.

Arthritis is estimated to occur in 65% to 90% of cases of Whipple disease, with approximately 25% of patients showing axial involvement, either sacroiliitis or spondylitis.⁵¹ Large joints are more commonly affected than small joints. The arthritis is migratory, and the same joint is not always affected multiple times. Joint destruction does not occur. Joint involvement tends to occur several years before development of other clinical signs of the disease, and the duration of involvement is transient, spanning from hours to days.⁵² Treatment of Whipple disease with antibiotics also results in resolution of joint symptoms.

POLYARTERITIS NODOSA

Polyarteritis nodosa (PAN) is a necrotizing vasculitis that affects predominantly medium-sized but also small arteries (Fig. 37.7) (see Chapter 155). There is no known cause of this vasculitis, although numerous infectious agents have been implicated in the pathogenesis. For example, PAN develops within the first 6 months of a hepatitis B virus infection as a result of immune complex formation.⁵³ PAN has also been associated with hepatitis C virus infection.⁵⁴ PAN causes transmural inflammation of blood vessels

Fig. 37.7 Frontal view obtained during mesenteric arteriography in a patient with polyarteritis nodosa who experienced a gastrointestinal bleed from a gastroduodenal artery aneurysm, which was embolized. There are microaneurysms in the branches of the superior mesenteric artery (large arrows) and areas of saccular vessel dilatation (small arrows). (Courtesy Jade Wong, MD.)

leading to fibrinoid necrosis and formation of cutaneous nodules along superficial arteries. PAN can manifest systemically with involvement of multiple organs, including the gastrointestinal tract, kidneys, joints, brain, skin, and heart. Patients often have systemic constitutional symptoms such as fever, fatigue, weight loss, arthralgias, and myalgias. The diagnosis is made clinically, with biopsy of an accessible lesion performed for confirmation. In most patients with PAN, results of ANCA serologic testing usually are negative.⁵⁵ Gastrointestinal symptoms usually affect the small intestine, manifesting in approximately 50% of patients with PAN.⁵⁶ The symptoms are highly variable, from postprandial periumbilical pain to nausea and vomiting secondary to bowel infarction and perforation. PAN is treated with systemic steroids and immunosuppressive drugs.

Joint disease can also result from PAN, with joint involvement more extensive the longer PAN is present. It is estimated that 30% of patients with PAN have arthralgias or arthritis at presentation.⁵³ Males tend to experience articular symptoms almost twice as frequently as women. The systemic manifestations of PAN, including joint symptoms, often resolve with treatment of PAN.

HENOCH-SCHÖNLEIN PURPURA

Henoch-Schönlein purpura (HSP) is an immunoglobulin A-mediated small vessel necrotizing vasculitis that is also characterized by fibrinoid destruction of blood vessels (see Chapter 161). HSP is the most common vasculitis of childhood, seen predominantly in children between the ages of 3 and 10 years following a streptococcal upper respiratory tract infection.⁵⁷ However, the disease occasionally manifests in adults, and the course is often more severe than the course in children. Males are nearly twice as likely to be affected as females.⁵⁸ HSP often presents with a tetrad of symptoms including nonthrombocytopenic palpable purpura around the buttocks and lower extremities, arthritis or arthralgias, abdominal pain, and renal disease, most commonly hematuria with or without proteinuria.⁵⁸ Any of the four major symptom complexes can be the initial presenting feature. Moreover, the classic tetrad of symptoms is not seen in each case. Diagnosis is usually based on clinical symptoms, but if there is any doubt, a skin biopsy can be performed to confirm the diagnosis. Since HSP is self-limiting in 50% of patients, some argue that supportive care is the only indicated therapy, whereas others contend that medical treatment with corticosteroids and immunosuppressants improves renal outcomes in patients with HSP.^{59,60}

The joint symptoms are the second most common manifestation of HSP, occurring in approximately 70% of patients,⁶¹ with a higher frequency in adult-onset HSP.⁶² In 25% of patients, the arthritis precedes the purpura by approximately 1 week.⁶³ The symptoms are transient and nondeforming, and vary from mild arthralgias to debilitating arthritis; however, inflammatory arthritis is more commonly seen than arthralgias alone. Larger joints

Simvastatin ^{72,75}	Ticlopidine ^{78,86}
Lansoprazole ⁸¹	Flutamide ⁷⁸
Omeprazole ^{75,80}	Sertraline ⁷⁸
Ranitidine ⁷⁸	Acarbose ⁷⁸

such as the ankles, knees, and wrists are more frequently affected. In one series, there was uniform involvement of the lower extremity joints, knees, ankles, and feet in all participants.⁵⁷ Retrospective studies have shown that HSP-associated arthritis is effectively relieved with corticosteroids.⁶³

BEHÇET SYNDROME

Behçet syndrome is a rare, chronic, multisystemic vasculitis involving small, medium, and large vessels of both the arterial and venous circulations, with a particular predilection for blood vessels in the oral and genital mucosa (see Chapter 159). Behçet syndrome is most frequently seen in the Middle East, Far East, and Mediterranean in patients 25 to 35 years of age. In a U.S. population-based study the estimated incidence was 0.38 per 100,000 population.⁶⁴ There is no known cause of this syndrome, but hypotheses include autoimmune effects, immune circulating complexes, and chemical agents.⁶⁵ Behçet syndrome has been associated with the HLA-B51/B5 risk allele.⁶⁶ A meta-analysis showed that carriage of the HLA-B51/B5 allele was associated with a 7% to 13% increase in the prevalence of genital, skin, and ocular involvement and a 30% relative risk reduction of gastrointestinal involvement.⁶⁷ Behçet syndrome is characterized by recurring and remitting symptoms that include oral aphthous ulcers, genital ulcers, and uveitis, as well as associated skin, joint, gastrointestinal, cardiac, and neurologic manifestations. Surgical resection of an aneurysm resulting from Behçet syndrome-mediated destruction is necessary in 10% of patients. Currently, there is not a specific diagnostic test for Behçet syndrome; diagnosis is based on clinical findings and recurrence of the disease over time. Treatments are customized to each patient's clinical symptoms and may include glucocorticoids, colchicine, 5-aminosalicylates, thalidomide, azathioprine, cyclophosphamide, and infliximab.^{68,69}

Joint manifestations occur in approximately 57% to 75% of patients with Behçet syndrome and are the presenting symptoms in 11% to 18% of cases.^{68,70} Large joints such as the knees and ankles are most commonly affected. Polyarthritis involving large and small joints occurs in 17% of cases, whereas monoarthritis and oligoarthritis occur in 11% and 16% of cases, respectively. The arthritis is self-limiting after a few weeks and does not cause permanent damage.

MICROSCOPIC COLITIS

Microscopic colitis, comprising collagenous colitis (CC) and lymphocytic colitis (LC), is characterized by chronic watery diarrhea. CC primarily affects older women at around 65 years of age; women are seven times more likely to be affected than men.⁷¹ LC affects middle-aged women, but the female-male ratio is lower, 2-3:1. In recent years the incidence of microscopic colitis appears to be increasing. Although the exact reason for the increase is unknown, current theories include increased clinical recognition of the disease through routine performance of random colonic biopsies in patients with chronic diarrhea and likely higher use of medications associated with microscopic colitis.⁷²⁻⁸¹ See Table 37.4 for a list of common medications associated with microscopic colitis.

The cause of microscopic colitis is unknown and is thought to be multifactorial, with the disease occurring in individuals who are susceptible to certain noxious luminal agents that result in microscopic mucosal inflammation. Clinically, CC and LC are indistinguishable from each other, causing chronic nonbloody, watery diarrhea that may be associated with diffuse abdominal pain and significant weight loss. Approximately 40% of patients with microscopic colitis have another associated autoimmune condition, most commonly a thyroid disorder, celiac disease, diabetes mellitus, or rheumatoid arthritis.⁷¹ Microscopic colitis is differentiated based on colonic mucosal biopsy of the colon and rectum; the endoscopic findings in both CC and LC are normal.⁸² CC manifests as excess subepithelial collagen

deposition with chronic mononuclear inflammation in the lamina propria, whereas LC causes increased intraepithelial lymphocytes but the collagen layer is normal. There are no known long-term complications of the disease or increased risk of colorectal cancer. Microscopic colitis is treated with antidiarrheals, bismuth subsalicylate, 5-aminosalicylates, budesonide, or corticosteroids with varying successes. Surgery rarely is indicated.

Articular symptoms accompany CC in rare cases, occurring in up to 7% of patients.⁸³ The arthritis is transient, nonerosive, and oligoarticular. Peripheral joints, including the metacarpophalangeal, proximal interphalangeal and wrist joints, are most commonly affected. The arthritis resolves upon treatment of the CC.⁸⁴

CONCLUSION

Extraintestinal involvement, particularly of the joints, is relatively common in patients with gastrointestinal disease. The cause of joint involvement is

not known but may relate to increased antigen presentation to the immune system secondary to increased gut permeability or the action of systemic cytokines on the joints. The list of gastrointestinal illnesses that affect the joints is extensive. The presentation of arthritis is highly variable, and arthritis (1) may affect the peripheral or axial joints; (2) may involve one, few, or many joints; and (3) may or may not be correlated with specific features of the underlying gastrointestinal symptoms. Most of the arthritides do not result in progressive joint destruction; improvement in the joint symptoms often coincides with treatment of the underlying disorder. The prognosis for many of these forms of arthritis is excellent. Internists, gastroenterologists, and rheumatologists need to be aware of the relationship between joint symptoms and gastrointestinal disease to improve accuracy of diagnosis and enhance clinical outcomes.

The kidney and rheumatic disease

■ DANIEL J. SALZBERG ■ MATTHEW R. WEIR, SR.

- Because kidney disease is frequently asymptomatic, routine testing is imperative.
- Many drugs used in rheumatology are potentially nephrotoxic.
- Patients with kidney disease experience distinctive joint and soft tissue complications.

INTRODUCTION

The kidneys are involved in many homeostatic functions, including maintenance of acid-base balance, electrolyte concentrations, and osmolarity; excretion of toxins and metabolic wastes; and elaboration of certain hormones, including erythropoietin, 1,25-dihydroxycalciferol, and renin. Unlike rheumatologic diseases, the signs and symptoms of kidney disease tend to not be obvious physical findings until late in the course of disease, so routine screening for renal manifestations is essential for preservation of renal function. [Table 38.1](#) presents a list of the renal syndromes that occur in persons with rheumatic diseases.

The functional unit of the kidney is the nephron, which consists of a glomerulus followed by a long network of tubules. The glomerulus has a somewhat unusual anatomy in that its capillary bed is sandwiched between two arteries. This explains why glomerulonephritis (GN) is a frequent manifestation of systemic vasculitides such as systemic lupus erythematosus (SLE), Henoch-Schönlein purpura, Churg-Strauss syndrome, microscopic polyangiitis, antineutrophilic cytoplasmic antibody (ANCA)-associated granulomatous vasculitis, and cryoglobulinemic vasculitis.

Manifestations of renal disease**Proteinuria**

Proteinuria usually reflects an increase in the permeability of the glomerular barrier to normally nonfiltered molecules, such as albumin. When proteinuria is severe, it is usually manifested as diffuse peripheral edema. However, if the proteinuria is of a lesser degree, it may not be associated with any symptoms or signs and is often detected only on urinalysis.

Heavy proteinuria is highly suggestive of a “hole” in the filter of the kidney (i.e., a glomerular lesion) and is classified as nephrotic syndrome. This syndrome is characterized by (1) nephrotic-range proteinuria, defined as 3.5 g/day/1.73 m² or greater; (2) hypoalbuminemia; (3) hypercholesterolemia; (4) edema; and (5) lipiduria. Nephrotic-range proteinuria is almost always due to a glomerular pathologic process inasmuch as tubulointerstitial kidney disease will result in a more modest degree of protein spillage.

Nephrotic syndrome is associated with a hypercoagulable state, which may be manifested clinically as stroke, deep venous thrombosis, or renal vein thrombosis. In patients with nephrotic syndrome, one must maintain a high index of suspicion for renal vein thrombosis because it is infrequently manifested as the classic triad of flank pain, overt hematuria, and worsening kidney function. Patients with SLE and nephrotic syndrome who have experienced previous episodes of thrombophlebitis are particularly at risk for renal vein thrombosis.

Hematuria

Hematuria is usually asymptomatic and not visible to the naked eye (i.e., microscopic hematuria). Therefore, it often goes unnoticed until a urinalysis is performed. Macroscopic or “gross” hematuria is suspected when the urine is red, brown, or tea colored. As with microscopic hematuria, macroscopic hematuria tends to be asymptomatic. Both microscopic and macroscopic

hematuria is seen in rheumatologic disorders as a feature of renal vasculitis or acute GN. However, hematuria is more frequently due to nephrolithiasis, urinary tract infection, trauma, prostatitis, genitourinary cancer, or benign prostatic hypertrophy ([Box 38.1](#)). Because the most common manifestation of genitourinary cancer is hematuria, its presence in an adult obligates an assessment for an underlying carcinoma.

Renal dysfunction

Renal failure is arbitrarily divided into acute, subacute, and chronic based on the time course. Acute kidney injury (AKI), previously termed acute renal failure, is evidenced by an elevation in the serum creatinine concentration that develops over days to weeks, whereas chronic kidney disease (CKD) extends over a period of months to years. With CKD, the symptoms of uremia tend to occur insidiously. Such symptoms include easy fatigability, daytime somnolence, nighttime sleep disturbances, nausea, anorexia, pruritus, easy bruising, mucosal bleeding, and dysgeusia. Because these symptoms are nonspecific, they are frequently attributed to other disorders, such as depression or hypothyroidism. They may not be attributed to AKI or CKD until some estimate of kidney function is obtained. Fluid retention or edema and a reduction in urine volume are not frequent features of CKD until an advanced stage of CKD is reached. As with CKD, the symptoms of AKI tend to be relatively nonspecific and depend on the underlying disease process. The constellation of worsening or new-onset hypertension, hematuria, and AKI suggests acute GN, vasculitis, or both.

Approach to patients with rheumatologic disease and suspected renal involvement

The approach to a patient with suspected renal disease requires a careful physical examination and a directed laboratory assessment. Individuals with kidney disease tend to be asymptomatic, and therefore one is particularly dependent on laboratory tests for detecting kidney involvement in systemic disease. By integration of laboratory and clinical findings, one can classify the kidney involvement into one of the renal syndromes listed in [Table 38.1](#).

Physical examination findings

Hypertension is a common consequence of kidney disease, including the glomerular damage seen with autoimmune disorders. Renovascular disease accounts for 10% to 45% of cases of acute, severe, or refractory hypertension, but for less than 1% of mild hypertension. Aggressive control of blood pressure is of paramount importance in all individuals with hypertension, particularly in those with underlying kidney disease. Treatment with an effective antihypertensive regimen that includes either an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin receptor blocker may prevent the progression of kidney disease.

Although dysfunction of several organs can be manifested as edema, this finding should trigger evaluation for proteinuria. With nephrotic syndrome, the distribution of edema tends to be generalized, unlike the distribution seen with congestive heart failure or cirrhosis. Despite massive proteinuria, edema does not develop in some patients as commonly seen with secondary focal segmental glomerulosclerosis (FSGS).

TESTING FOR KIDNEY DISEASE**Proteinuria**

Ordinarily, a normal healthy adult excretes 84 ± 24 mg of protein per day. The small amount of protein that appears in normal urine consists of albumin, immunoglobulins, products of hormone metabolism, and Tamm-Horsfall proteins.

TABLE 38.1

Renal syndromes in patients with rheumatic diseases*

Renal syndrome	Clinical features	Laboratory features	Course
Asymptomatic urinary abnormalities or "subacute"	None	Proteinuria and/or microscopic hematuria	Persistent; may evolve to nephrotic
Nephrotic syndrome	Edema ± ascites, effusions	Proteinuria >3.5 g/day, low serum albumin and elevated cholesterol levels	Persistent or remitting and relapsing
Acute nephritic syndrome	Reduced urine output, ± discolored urine, ± fluid retention	Elevated plasma creatinine, microscopic hematuria, red cell casts	Poststreptococcal form resolves; acute episodes in lupus may recur
Rapidly progressive glomerulonephritis	Progressive oliguria, discolored urine, systemic symptoms	Rapidly rising plasma creatinine level, falling GFR, hematuria, red cell casts	Progresses to renal failure in weeks or months
Persistent "subacute" glomerulonephritis (mixed nephrotic/nephritic)	± Edema, ± discolored urine, ± hypertension	Proteinuria, ± low serum albumin, microscopic hematuria	Persistent; may progress to renal failure (in years)
Renal vasculitis	± Discolored urine, ± visible hematuria, ± hypertension	Elevated plasma creatinine, proteinuria, hematuria, ± red cell casts	Variable with treatment; may mimic RPGN
Tubulointerstitial nephritis	± Discolored urine	Elevated plasma creatinine, sterile pyuria (white blood cells), microscopic hematuria	Acute (resolves in months) or chronic (persistent)
Chronic renal failure (mild to moderate)	Few or none, ± hypertension	Elevated plasma creatinine, reduced GFR, ± urinary abnormalities	Persistent; renal failure usually worsens
Chronic renal failure (severe)	Subclinical to severe uremic symptoms, ± hypertension	Plasma creatinine >6 mg/dL, GFR <10 mL/min, ± urinary abnormalities	Imminent need for dialysis or renal transplantation

*Same of the principal syndromes of renal involvement are shown. For each syndrome, typical clinical signs and symptoms are listed, together with the distinguishing findings on routine laboratory screening. Some degree of proteinuria is present in the vast majority of all these syndromes and is mentioned in the table only when it is a constant and defining feature of the syndrome. The typical course of evolution of each syndrome over time is also shown because it helps characterize the syndromes and is integral to the definition of some of them (e.g., RPGN). This information cannot be used as a basis for prognosis in individual cases, which varies widely. The laboratory features listed here are those obtainable only from tests used routinely for renal surveillance (blood chemistry, urinalysis, and urine microscopy), plus the results of 24-hour urine chemistry (timed protein quantitation and creatinine clearance to estimate GFR). The latter should be obtained at the initial evaluation of patients at risk for renal involvement, whenever new elevations in proteinuria or plasma creatinine are detected, or periodically in nephrotic and renal failure patients. Laboratory studies beyond those listed are appropriate for full diagnosis in all cases and may include additional chemical and serologic tests, imaging studies, and histologic evaluation of renal biopsy material. GFR, glomerular filtration rate (measured by creatinine clearance or other methods); RPGN, rapidly progressive glomerulonephritis.

Glomerular proteinuria

Glomerular proteinuria is typically in the nephrotic range, with associated hypoalbuminemia and lowered intravascular oncotic force, which often results in the development of edema. However, whether edema develops depends on other factors, including nutritional status and the type of underlying nephropathology.

The degree of proteinuria, together with the degree of tubulointerstitial damage, is the most powerful predictor of progression of CKD, regardless of the underlying disease process. Therefore, every effort must be made to minimize or extinguish proteinuria. ACE inhibitors or angiotensin receptor blockers (or both) should be considered first-line agents in the treatment of all cases of proteinuria.

Tubular proteinuria

Tubular proteinuria occurs in settings in which glomerular protein sieving is normal but tubular reabsorption of normally filtered low-molecular-weight proteins is impaired. As opposed to glomerular diseases, the range of proteinuria is much lower, usually in the range of 1 to 2 g/day. Tubular proteinuria can be associated with tubulointerstitial disease resulting from uric acid nephropathy, Sjögren syndrome, essential hypertension, and drugs such as aminoglycoside antibiotics.

Measurement of proteinuria

After protein spillage has been detected, the absolute amount of protein excreted should be quantified because this will help distinguish between glomerular and tubulointerstitial disease. Quantification is accomplished either by a timed (usually 24-hour) urine collection or by analysis of a spot urine sample. The 24-hour urine collection had been the "gold standard" method for quantification but has been replaced by the protein-to-creatinine ratio on a "spot" urine sample. A protein-to-creatinine ratio of 0.2 correlates with a protein excretion rate of approximately 200 mg/day, a ratio of 2.0 with 2000 mg/day, and a ratio of 3.5 with 3500 mg/day (i.e., nephrotic-range proteinuria). Detection of microalbuminuria has become extremely important in view of the appreciation of its clinical correlation with cardiovascular and kidney disease. The normal range of the urine albumin excretion rate is less than 20 mg/min on an overnight timed urine collection or 30 mg/day on a 24-hour collection. The abnormal microalbuminuria range is 20 to 200 mg/min (30 to 300 mg/day). Values higher than 300 mg/day suggest

"overt" proteinuria. First studied in diabetic patients, microalbuminuria has now been found to be a harbinger of renal involvement in many other diseases (see later). Microalbuminuria is present in the majority of patients with SLE, even in those with apparently normal urine and kidney function¹; biopsy may reveal histologic changes, and overt nephritis subsequently develops in some of these patients.

Hematuria

Hematuria, unlike proteinuria, may arise from anywhere in the urinary tract (see Box 38.1). Hematuria can be divided into upper tract bleeding (i.e., glomerular or tubulointerstitial) and lower tract bleeding (i.e., extrarenal). Diagnostic clues such as red blood cell (RBC) casts, significant proteinuria, or abnormal kidney function suggest upper tract bleeding. In subjects with rheumatic disease, microscopic hematuria will often be accompanied by proteinuria, which suggests upper tract bleeding.

Red blood cells

RBC morphology offers a clue to the site of origin of the hematuria. Non-glomerular hematuria will typically have less than 1% dysmorphic erythrocytes. However, glomerular hematuria usually contains a high proportion of abnormally shaped RBCs with vesicle-shaped protrusions (acanthocytes) and considerable anisocytosis (Fig. 38.1).

Other urine microscopy findings

Pyuria, or the presence of white blood cells (WBCs), suggests an infection within the genitourinary tract and mandates urine culture. Sterile pyuria has classically suggested renal tuberculosis but also can be seen with tubulointerstitial nephritis, such as occurs with allergic interstitial drug reactions, Sjögren syndrome, and lupus interstitial nephritis. As an indicator of acute interstitial nephritis, eosinophiluria has limited sensitivity.

Urinary casts are formed in the renal tubules from an aggregation of proteins, primarily Tamm-Horsfall proteins. Not all casts are pathologic; for example, hyaline casts can be seen in normal urinary sediment. When intact cells or cellular debris become trapped within the protein matrix, various "cylindrical casts" result: "muddy brown" granular casts with or without renal tubule epithelial casts are associated with acute tubular necrosis; WBC casts are classically associated with pyelonephritis or interstitial nephritis; and RBC casts are pathognomonic of intraparenchymal bleeding, such as

BOX 38.1 CAUSES OF HEMATURIA

Glomerulonephritis and other glomerular diseases
 IgA nephropathy
 Membranoproliferative (mesangiocapillary) glomerulonephritis
 Mesangial proliferative glomerulonephritis

ANCA, antineutrophilic cytoplasmic antibody.

from GN or vasculitis. Broad and waxy casts, which are both acellular, strongly suggest CKD.

With nephrotic-range proteinuria, one may see lipid droplets. If present within renal tubule epithelial cells, they are called oval fat bodies. These fat bodies, when viewed under polarized light, have a characteristic “Maltese cross” appearance.

Kidney function testing

Kidney function is a nonspecific term usually applied to the principal function of the kidney: filtration of wastes by the glomerulus (i.e., the glomerular filtration rate [GFR]). The GFR is generally considered to be the best index of overall kidney function because an impairment in GFR correlates with the severity of structural abnormalities observed on biopsy specimens. A normal GFR is approximately 130 mL/min in men and 120 mL/min in women, but it also depends on age, sex, and body size. The GFR is not an all-inclusive index of function, and many kidney diseases do not alter the GFR.

Plasma creatinine measurement

The plasma creatinine concentration (P_{CR}) is a simple and useful correlate of GFR. Plasma creatinine is an inexpensive and widely used test of kidney function; when it is repeated serially in an individual, it may give significant insight into changes in kidney function.

Despite its appeal, significant problems arise when using P_{CR} as a sole marker of GFR. Specifically, in the lower range, small increases in P_{CR} reflect major reductions in the GFR (Fig. 38.2). Thus, in some cases up to half of renal function can be lost before P_{CR} exceeds the upper limits of normal. Also, when the GFR changes abruptly, output no longer equals input, and it may take several days before the system achieves a new steady state. Because 10% to 20% of creatinine is excreted by tubular secretion, in some cases elevations in P_{CR} are unrelated to changes in the GFR. Drugs that block tubular secretion, such as trimethoprim and cimetidine, are associated with such elevations in P_{CR} despite not affecting glomerular function. Other drugs such as cefoxitin and flucytosine may cause false elevations in creatinine measurements by interfering with the laboratory chemical assays for creatinine. Finally, some disease states are associated with hyperexcretion of creatinine by the proximal tubule, as is the case with sickle cell disease.

Another concern about the use of P_{CR} as the sole marker of kidney function is that although the GFR decreases markedly with age, P_{CR} barely rises (Fig. 38.3). This is due to a decrease in creatinine production as muscle mass decreases with age. This problem also affects other states in which muscle mass is lost, such as anorexia nervosa, amputations, and chronic illnesses.

Stages of chronic kidney disease

The National Kidney Foundation has established stages of CKD, as listed in Table 38.2.²

Tests for renal tubular dysfunction

The renal tubular disorders most likely to be encountered in patients with rheumatic disease are renal tubular acidosis (RTA) and either hypokalemia or hyperkalemia. These disorders are seen in several autoimmune diseases, including the interstitial nephritis of SLE and Sjögren syndrome. These problems develop in about 10% of patients with SLE, although subclinical defects in the handling of potassium, sodium, or hydrogen ions can be demonstrated in up to 60% of cases.³ RTA is manifested as a hyperchloremic, non-anion gap acidosis with a low plasma bicarbonate concentration. With distal, type 1 RTA, ammonium ion secretion into urine is reduced. The RTA seen in lupus is usually due to proton secretion defects in the distal tubules.³

Persistent hyperkalemia is invariably associated with renal tubular dysfunction, which results in impaired urinary potassium excretion. This occurs with advanced kidney failure, with any cause of hypoaldosteronism, or with marked volume depletion.

Hypocomplementemia and kidney disease

Measurements of C3 and C4 are often used to narrow the differential diagnosis of kidney diseases. The list of GNs associated with hypocomplementemia includes lupus nephritis, membranoproliferative GN (MPGN), mixed cryoglobulinemia, postinfectious GN, membranous nephropathy secondary to hepatitis B infection, and serum sickness. Complement levels tend to be normal in ANCA-associated granulomatous vasculitis, microscopic polyangiitis, Goodpasture syndrome, and Henoch-Schönlein purpura.

Renal imaging**Kidney ultrasonography**

Ultrasonography is the most commonly used technique to image the kidneys because it is noninvasive and does not depend on kidney function. It allows

Fig. 38.1 Microscopy of urine. (a) Acanthocytes are seen through the microscope, which indicates a renal (probably glomerular) origin of the hematuria (phase contrast, original magnification $\times 640$). (b) Acanthocytes seen on scanning electron microscopy. Details of the “knobs” and protrusions can be seen. (c) A tubular cast containing red cells, which usually indicates a glomerular origin of concomitant hematuria and, in general, an active proliferative/infiltrative glomerular disease (phase contrast, original magnification $\times 400$). (a and c, Courtesy Dr. G.B. Fogazzi; b, reproduced with permission of Blackwell Science from Fasset RG, Owen JE, Fairley J, et al. Urinary red-cell morphology during exercise. *BMJ* 1982;285:1455-7.)

Fig. 38.2 As the glomerular filtration rate (GFR) decreases, plasma creatinine rises, but in a hyperbolic fashion, so plasma creatinine levels become abnormal (normal range shaded) only after considerable loss of renal function. One way of compensating for this hidden information is to use the reciprocal of plasma creatinine, which is approximately linear.

determination of kidney size, the degree of echogenicity, anatomic abnormalities, and obstruction.

Assessment of the renal vasculature

To assess for renal vasculitis, the best imaging studies include angiography, magnetic resonance angiography (MRA), and computed tomography (CT). For assessment of the renal vasculature in patients with rheumatic disease, duplex Doppler ultrasonography is better at detecting stenosis of the major branches of the renal arteries than at demonstrating vasculitis or aneurysms. Renal vein thrombosis may be diagnosed by Doppler ultrasonography, but its sensitivity and specificity are suboptimal; spiral CT and MRA are better, but the gold standard remains selective venography.

Kidney biopsy

Indications

Percutaneous kidney biopsy is an essential tool for determining the diagnosis, prognosis, and treatment options for patients with kidney disease. One of the strongest indications for performing kidney biopsy is in the setting of rapidly progressive GN (RPGN). The syndrome is defined clinically as a rapid decline in kidney function associated with active urinary sediment, typically with RBC casts. Delays in diagnosis and subsequent initiation of treatment may result in irreversible loss of kidney function. Common rheumatologic causes of RPGN include lupus, ANCA-related vasculitis, and Henoch-Schönlein purpura. Other indications for performing biopsy in patients with rheumatic disease include unexplained AKI, acute nephritic syndrome, persistent proteinuria, persistent hematuria, and nephrotic syndrome.

Renal Histopathology

An adequate kidney biopsy will result in two or three cores of kidney tissue, which are examined by light microscopy (LM), immunofluorescence (IF) microscopy, and electron microscopy (EM).

Fig. 38.3 The “hidden” reduction in renal function with age. Although normal creatinine clearance decreases dramatically with age to a mean of just 40 mL/min in the very elderly, the plasma creatinine value remains constant up to 100 years of age because of a concomitant reduction in excretion (and, by inference, production) of creatinine as a result of a reduction in muscle mass. (Data from Kampmann JM, Siersbaek-Nielsen K, Kristensen M, Hansen JM. Rapid evaluation of creatinine clearance. *Acta Med Scand* 1974;196:517-20.)

TABLE 38.2

Chronic kidney disease: a clinical action plan

Stage	Description	GFR (mL/min/1.73 m ²)	Action*
1	At increased risk	≥90 (with CKD risk factors)	Screening CKD risk reduction
	Kidney damage with normal or ↑ GFR	≥90	Diagnosis and treatment, treatment of comorbid conditions, slowing progression, CVD risk reduction
2	Kidney damage with mildly ↓ GFR	60-89	Estimating progression
3	Moderately ↓ GFR	30-59	Evaluation and treating complications
4	Severely ↓ GFR	15-29	Preparation for kidney replacement therapy
5	Kidney failure	<15 (or dialysis)	Replacement (if uremia present)

Stages 1 through 5 identify patients who have CKD; the first row designates individuals who are at increased risk for the development of CKD. CKD is defined as either kidney damage or GFR lower than 60 mL/min/1.73 m² for 3 or more months. Kidney damage is defined as pathologic abnormalities or markers of damage, including abnormalities in blood or urine tests or imaging studies.

*Includes actions from preceding stages.

CKD, chronic kidney disease; CVD, cardiovascular disease; GFR, glomerular filtration rate.

Patterns seen on immunofluorescence microscopy

Three patterns are seen on IF microscopy: linear, granular, and pauci-immune. The primary cause of a linear pattern is antibodies directed against the glomerular basement membrane (GBM), as is the case with anti-GBM disease. When associated with pulmonary hemorrhage, this constellation of findings is known as Goodpasture syndrome. In contrast to a linear deposition, diseases associated with immune complex deposition will have a granular, “lumpy-bumpy” appearance. This occurs with SLE and postinfectious GN. The term *pauci-immune* implies that no or minimal immunoglobulins are found on IF microscopy, and it is seen with ANCA-associated granulomatous vasculitis, microscopic polyangiitis, and other ANCA-related vasculitides.⁴

Transmission EM allows significant enhanced resolution in comparison to LM and can delineate the precise location and size of electron-dense deposits. Deposits can be divided into (1) subepithelial, in which accumulation of material occurs on the external aspect of the GBM, between the basement membrane and the visceral epithelial cell; (2) subendothelial, in which accumulation occurs between the GBM and the fenestrated endothelial cell; and (3) transmembranous or intramembranous, in which the deposits are within the GBM. Identification of subendothelial deposits correlates with the wire loop seen on LM in patients with SLE-related nephritis. EM can also reveal other ultrastructural features of diagnostic importance,

such as tubuloreticular structures, or so-called viruslike particles, in the glomerular endothelial cells of patients with SLE-associated nephritis.

Interpretation

The renal cortical parenchyma contains three different domains: the glomeruli, the tubules and interstitium, and the vasculature. Small- and medium-vessel vasculitis can be distinguished from changes caused by atherosclerosis, hypertension, diabetes mellitus, or systemic sclerosis. Tubulointerstitial changes can range from acute inflammation with edema to chronic fibrosis with scarring or may include granuloma formation, as seen with renal sarcoidosis.

Terminology

Specific terms have been assigned to describe the pattern of involvement in one glomerulus (segmental or global), and other terms have been assigned to describe the proportion of glomeruli involved in a pathologic process (focal or diffuse). The term *focal* is applied when less than 50% of all glomeruli are involved, and the term *diffuse* is used when more than 50% of all glomeruli are involved. The term *segmental* is applied to a lesion that involves a portion of one particular glomerulus, and the term *global* is applied to a lesion that involves the whole glomerulus. For example, if a total of 20 glomeruli are examined under LM and only 5 of them have pathologic changes, this would be referred to as a focal lesion. If these five

TABLE 38.3
Morphologic terminology in nephropathology

		All glomeruli	
		Focal (<50%)	Diffuse (>50%)
One glomerulus	Segmental (<50%)	Focal-segmental	Diffuse-segmental
	Global (≥50%)	Focal-global	Diffuse-global

glomeruli have only partial involvement, the process is further defined as segmental (Table 38.3).

Glomerular pathology is divided into primary, or idiopathic, lesions and secondary lesions. Five histologic patterns of primary glomerular lesions are recognized:

1. Minimal change disease: as its name implies, minimal change disease has minimal to no pathologic changes visible on LM or IF. In rheumatology practice it may be seen as a complication of the use of nonsteroidal antiinflammatory drugs (NSAID) (see later).
2. FSGS: This condition initially affects only a portion of each glomerulus and tends to involve some but not all the glomeruli. FSGS can be manifested as either nephritic or nephrotic syndrome or as a progressive decline in the GFR. Secondary causes of FSGS include human immunodeficiency virus (HIV) infection, reflux nephropathy, and obesity.
3. Membranous GN: On LM, the characteristic finding of membranous GN is thickening of the capillary walls because of subepithelial deposits. Membranous GN tends to be manifested as massive proteinuria (nephrotic syndrome) and edema. Secondary causes of membranous GN include SLE (class V nephritis), mixed connective tissue disease (MCTD), gold therapy, solid tumors, and hepatitis B infection.
4. Mesangial proliferative GN: On LM, the mesangium is expanded with increased cellularity and matrix. IF microscopy may demonstrate mesangial deposition of IgA, IgM, or IgG, with or without C3. When the predominant finding on IF is IgA deposits, the lesion is referred to as IgA nephropathy or Berger disease. The clinical findings of mesangial proliferative GN are variable. Important secondary causes include lupus nephritis, Henoch-Schönlein purpura (systemic Berger disease), rheumatoid arthritis, and ankylosing spondylitis.
5. MPGN: This lesion has also been called mesangiocapillary GN and is divided into type 1, type 2 (dense deposit disease), and type 3 based on findings on microscopy. They can all be manifested as RPGN, as macroscopic hematuria, less commonly as nephrotic syndrome, or as isolated proteinuria or microscopic hematuria (or both). Typical LM findings include capillary wall thickening because of the presence of deposits, which frequently take the form of a duplicated or split basement membrane (double contours or “tram tracking”). Secondary causes of MPGN include lupus (class III and IV) and a rare form associated with hypocomplementemic partial lipodystrophy.

Another significant abnormal finding is the presence of cells, fibrin, or collagen in the urinary space of the glomeruli. When this process involves more than 50% of the circumference of the glomerular tuft, it is termed a *crescent* (fibrous, fibrocellular, or cellular crescent, depending on the predominant finding). The presence of crescents is a marker for severe kidney injury and is usually the pathologic equivalent of the clinical syndrome of RPGN. Crescentic GN may be associated with other forms of primary GN, such as MPGN or IgA nephropathy, or with secondary forms of GN, such as SLE and ANCA-associated granulomatous vasculitis.

RHEUMATOLOGIC DISEASES AFFECTING THE KIDNEYS (Table 38.4)

Systemic lupus erythematosus

Kidney involvement is common in SLE, with approximately a third of patients initially seen by a nephrologist rather than a rheumatologist. The incidence of lupus nephritis probably exceeds 90% because some kidney involvement may be silent.⁵ Subgroups of patients with SLE at increased risk for the development of nephritis include men younger than 33 years at the time of diagnosis of SLE and non-European Americans.⁶ The presence of anticardiolipin antibody activity correlates with a worse kidney prognosis.⁷

The principal different renal lesions are summarized in Table 38.4. The World Health Organization's classification of lupus nephritis has been modified⁸ (Table 38.5). The primary advantage of the revised classification system is that it provides a clearer description of the lupus nephritis classes.

Treatment and prognosis are different for each type of nephritis.⁹ Additionally, transitions between the different classes of GN occur frequently but do not take place in a stepwise fashion. Most renal abnormalities emerge soon after diagnosis. In one study of 1000 patients seen in rheumatologic practice, kidney involvement was initially present in 16% and increased to 50% during follow-up.¹⁰ However, even if a subject does not have overt nephropathy, urinalysis and determination of the GFR (see earlier) should be performed routinely. Acute nephritis exacerbations require immediate evaluation and usually a kidney biopsy. Unfortunately, renal vasculitis and thrombotic microangiopathy are rarely demonstrable on biopsy specimens. Renal vein thrombosis in patients with lupus nephritis may similarly be clinically inapparent.

Overt distal RTA and hyperkalemia develop in about 10% of patients with lupus nephritis, although subclinical defects are present in a large number of individuals. The hyperkalemia may be exacerbated by the use of potassium-sparing diuretics or agents that interfere with blockade of the renin-angiotensin system, such as ACE inhibitors and angiotensin receptor blockers. Strategies to decrease hyperkalemia include limiting dietary potassium intake, use of fludrocortisone, and use of loop diuretics.

Mixed connective tissue disease

Though originally described as a syndrome without renal involvement, MCTD is now recognized as having kidney involvement in 25% to 50% of cases.¹¹ The most common lesion is membranous GN,¹¹ which is manifested similar to that seen in SLE. Individuals with more systemic manifestations from MCTD appear to be at higher risk for kidney involvement than those without systemic involvement. Hypertensive crises similar to those seen with “scleroderma kidney” may also develop in patients with MCTD.

Rheumatoid arthritis

The existence of a glomerulopathy associated with untreated rheumatoid arthritis is now generally accepted,¹² in addition to renal disease secondary to medications used to treat the underlying disorder. The most common kidney lesion is mesangial proliferative GN, but other renal lesions include membranous GN, focal proliferative GN, and secondary amyloidosis.¹² Rheumatoid arthritis may also be manifested as RPGN with either crescentic¹³ or necrotizing GN¹⁴ or as pauci-immune GN.¹⁵ Nephrotic syndrome in patients with rheumatoid arthritis most often reflects either membranous GN from gold or penicillamine toxicity or the development of systemic amyloidosis with glomerular involvement¹² (see later).

Sjögren syndrome

Sjögren syndrome typically does not result in glomerular pathology but more frequently produces an interstitial nephritis and defects in tubular function. The presence of interstitial nephritis in association with eye findings should raise the specter of the syndrome of tubulointerstitial nephritis associated with uveitis (TINU). This tubular pathology associated with Sjögren syndrome can be manifested clinically as a reduction in the GFR, distal RTA, or hypokalemia or as mild nephrogenic diabetes insipidus.¹⁶ MPGN and membranous GN have been diagnosed in patients with Sjögren syndrome.¹⁷

Relapsing polychondritis

Kidney disease is a variable feature of relapsing polychondritis and may be manifested as proteinuria, hematuria, or a decline in kidney function. Lesions accompanied by relapsing polychondritis may be associated with coexisting disease such as SLE. Renal pathology has included mesangial proliferative GN, crescentic necrotizing GN, and tubulointerstitial nephritis.¹⁸

Behçet disease

Kidney involvement in Behçet disease appears to be less frequent than in other types of vasculitis. However, there is an association with focal or diffuse proliferative and membranous GN.¹⁹ Amyloidosis is a more common renal complication of Behçet disease and may be manifested as nephrotic syndrome. Intrarenal microaneurysms have also been described in association with Behçet disease. In one study, urinary abnormalities (proteinuria,

■ TABLE 38.4

Principal types of renal pathology in the rheumatic diseases

	Glomerular diseases	Renal vascular diseases	Tubulointerstitial diseases
Systemic lupus erythematosus	Mesangial glomerulonephritis (WHO class II) Focal proliferative glomerulonephritis (WHO class III) Diffuse proliferative glomerulonephritis (WHO class IV), including membranoproliferative glomerulonephritis (mesangiocapillary glomerulonephritis) and crescentic and necrotizing glomerulonephritis (WHO class V)	Vasculitis of the kidney Thrombotic microangiopathy (with thrombotic thrombocytopenic purpura or anticardiolipin syndrome) “Lupus vasculopathy” (see text) Renal vein thrombosis	Lupus tubulointerstitial nephritis Drug induced (NSAIDs, cyclosporine, etc.) Membranous glomerulonephritis
Mixed connective tissue disease	Membranous glomerulonephritis Mesangial glomerulonephritis	“Scleroderma kidney” (see later)	
Rheumatoid arthritis	Focal proliferative glomerulonephritis Crescentic necrotizing glomerulonephritis (with vasculitis) Membranous glomerulonephritis (gold, penicillamine) Renal amyloidosis (see later)	Vasculitis (rheumatoid) of the kidney Other drug induced (NSAIDs, methotrexate, cyclosporine, etc.)	Analgesic nephropathy (NSAIDs)
Sjögren syndrome	Membranoproliferative glomerulonephritis (mesangiocapillary glomerulonephritis) (with cryoglobulinemia)		Lymphocytic tubulointerstitial nephritis (with hypokalemic renal tubular acidosis)
Relapsing polychondritis	Mild mesangial glomerulonephritis Focal sclerosing glomerulonephritis		Tubulointerstitial nephritis
Behçet disease	Crescentic glomerulonephritis or milder proliferative glomerulonephritis Renal amyloidosis (see later)	Renal artery aneurysms and intrarenal microaneurysms	
Polyarteritis nodosa (classic)	Ischemic sclerosis of glomeruli	Arteritis and aneurysms of medium-sized vessels	
Microscopic polyarteritis (polyangiitis)	Focal necrotizing and crescentic glomerulonephritis (pauci-immune)	Vasculitis of small vessels (arterioles, capillaries, and venules)	
ANCA-associated granulomatous vasculitis	Focal necrotizing and crescentic glomerulonephritis (pauci-immune)	Vasculitis of small vessels (arterioles, capillaries, and venules)	Granulomas, lymphocytic infiltrates (periglomerular)
Churg-Strauss syndrome	Focal glomerulonephritis Focal necrotizing and crescentic glomerulonephritis	Vasculitis	Granulomas, eosinophil infiltrates
Essential mixed cryoglobulinemia	Cryoglobulinemic glomerulonephritis Membranoproliferative glomerulonephritis	Small-vessel vasculitis	Tubulointerstitial nephritis (mesangiocapillary glomerulonephritis)
Henoch-Schönlein purpura	Diffuse proliferative glomerulonephritis with mesangial IgA deposits		
Ankylosing spondylitis	Focal proliferative glomerulonephritis with mesangial IgA deposits (mesangial IgA nephropathy) Renal amyloidosis (see later)		
Reactive arthritis	Focal proliferative glomerulonephritis with mesangial IgA deposits (mesangial IgA nephropathy)		
Progressive systemic sclerosis (“scleroderma”)	Ischemic glomeruli	Concentric layered thickening of the arterial walls with narrowed lumens	
Amyloidosis	Mesangial expansion because of the accumulation of amyloid fibrils		Peritubular amyloid deposits
Gout (chronic urate nephropathy)			Chronic interstitial inflammation and fibrosis

ANCA, antineutrophilic cytoplasmic antibody; NSAID, nonsteroidal antiinflammatory drug; WHO, World Health Organization.

hematuria, or both) were present in about 10% of patients, but serious kidney lesions developed in less than 1%.²⁰

Classic polyarteritis nodosa

The kidneys are the organs most commonly involved in patients with polyarteritis nodosa, which leads to hypertension and a variable decline in the GFR. Patchy cortical infarctions may be present, and renal artery aneurysms may rupture. GN is not a feature of polyarteritis nodosa because it tends to not be a small-vessel disease.

ANCA-associated vasculitides

ANCA-associated granulomatous vasculitis, microscopic polyangiitis, and idiopathic pauci-immune GN probably represent the spectrum of disease manifestations of the ANCA-associated vasculitides. Classic ANCA-associated granulomatous vasculitis involves the upper and lower respiratory tracts and the kidney. When the vasculitis has more limited systemic involvement but still affects the kidney, it is termed *microscopic polyangiitis*. When only the kidneys are affected by the vasculitis, the condition is termed *idiopathic pauci-immune GN*. The view that these three entities

TABLE 38.5

World Health Organization classification of lupus nephritis

Class	Description
Class I	Mesangial immune deposits without mesangial hypercellularity
Class II	Mesangial immune deposits with mesangial hypercellularity
Class III Subdivisions for active and sclerotic lesions	Focal glomerulonephritis (involving <50% of the total number of glomeruli)
Class IV Subdivisions for active and sclerotic lesions	Diffuse glomerulonephritis (involving ≥50% of the total number of glomeruli)
Class IV-S Subdivisions for active and sclerotic lesions	Segmental involvement
Class IV-G Subdivisions for active and sclerotic lesions	Global involvement
Class V	Membranous
Class VI	Advanced sclerosing lesions

Data from Weening JJ, D'Agati VD, Schwartz MM, et al. The classification of glomerulonephritis in systemic lupus erythematosus revisited. *Kidney Int* 2004;65:521-30.

represent a spectrum of forms of a unified disease is supported by several facts:

1. A positive test for ANCA is typically present in all three conditions.
2. The glomerular pathology is indistinguishable.
3. Typical pulmonary lesions consistent with ANCA-associated granulomatous vasculitis may develop later in patients in whom idiopathic pauci-immune GN or microscopic polyangiitis is diagnosed.
4. Systemic manifestations, including kidney involvement, may develop later in patients with “limited” ANCA-associated granulomatous vasculitis in which the clinical findings are isolated to the pulmonary system.

The renal lesion in these conditions is typically manifested as RPGN. Renal vessels other than glomerular capillaries can also be involved by the necrotizing vasculitis.

Allergic granulomatosis and angiitis, better known as Churg-Strauss syndrome, is typified by allergic rhinitis, asthma, eosinophilia, and small-vessel vasculitis. As in ANCA-associated granulomatous vasculitis and microscopic polyangiitis, patients tend to be ANCA positive. Although the most common organ involved is the lung, kidney involvement occurs more frequently than previously thought, with a prevalence as high as 84%.²¹ Unlike ANCA-associated granulomatous vasculitis, renal failure is rare. The predominant glomerular pathology is FSGN, and it may be associated with necrotizing features and crescents.²¹ Granulomas and eosinophilic infiltrates in the kidney are infrequent.

Essential mixed cryoglobulinemia

Essential mixed cryoglobulinemia (formerly known as Meltzer syndrome) is often an epiphenomenon of a chronic viral infection, such as hepatitis C or HIV infection. Cryoglobulins are immunoglobulins that precipitate in the cold with deposition of antigen-antibody complexes in small and medium-sized arteries. Such deposition results in hypocomplementemia, palpable purpura, arthralgias, hepatosplenomegaly, and peripheral neuropathy. Kidney involvement occurs in upward of 60% of cases of mixed cryoglobulinemia.²² It can be manifested as asymptomatic hematuria and proteinuria but may progress to nephrotic-range proteinuria or deterioration of kidney function. Histologic examination of the kidney reveals MPGN with some unique features.²³ The majority of cryoglobulin deposits have a characteristic substructure containing curved annular-tubular structures that measure approximately 30 nm in diameter and look like a “fingerprint” (Fig. 38.4).

Henoch-Schönlein purpura

Henoch-Schönlein purpura is a small-vessel vasculitis characterized by deposition of IgA-containing immune complexes in tissue. It more

Fig. 38.4 Electron micrograph of a subject with cryoglobulinemia demonstrating electron-dense deposits of tubular fibrils in a “fingerprint” appearance (arrows).

frequently affects children than adults and has a classic tetrad of rash (palpable petechiae or purpura), arthralgias, abdominal pain, and kidney disease. The clinical severity of kidney disease varies from mild proteinuria and hematuria to the development of nephrotic syndrome or RPGN. The most common glomerular lesion seen in patients with Henoch-Schönlein purpura is mesangial proliferative GN, which has the characteristic finding of moderate to intense diffuse deposits of IgA in the mesangium. Less commonly, it can be manifested as crescentic GN. Henoch-Schönlein purpura-associated nephritis is an important cause of end-stage renal disease (ESRD) in children. In a retrospective, single-center study that examined kidney sequelae in adult patients with Henoch-Schönlein purpura and biopsy-proven cutaneous vasculitis, renal sequelae more commonly developed in patients with hematuria at disease onset or in those with renal involvement during the course of the disease.²⁴

The “seronegative spondyloarthritis” (ankylosing spondylitis, reactive arthritis)

The spondyloarthritis ankylosing spondylitis and reactive arthritis are infrequently associated with IgA nephropathy.²⁵ Clinically, this can be manifested as microscopic hematuria with or without a progressive decline in the GFR. Ankylosing spondylitis may also be complicated by the development of secondary amyloidosis.²⁶ These patients tend to initially be seen with nephrotic syndrome, which can progress to ESRD.

Progressive systemic sclerosis (scleroderma)

Scleroderma causes progressive mucoid thickening of the walls and narrowing of the vascular lumen of arteries, which results in severe hypertension and ischemic kidney disease. Diminished kidney blood flow is an early manifestation of scleroderma and appears before the development of hypertension, urinary abnormalities, or renal failure. “Scleroderma renal crisis” is characterized by acute renal failure associated with marked hypertension in the setting of relatively bland urinary sediment. There appears to be a significant association between antecedent high-dose corticosteroid therapy and the development of scleroderma renal crisis.²⁷ Kidney biopsy specimens have arterial changes that resemble thrombotic microangiopathy with edematous arteriolar intimal thickening and fibrinoid necrosis. Another classic finding seen on histology is “onionskin” concentric hypertrophy in the interlobular arteries. Because the hypertension is primarily due to ischemic activation of the renin-angiotensin system, ACE inhibitors are the mainstays of treatment.²⁸ Renal crisis will develop in 10% to 15% of patients with scleroderma, but a much larger percentage will have some kidney involvement.²⁹

Nephrogenic systemic fibrosis

Nephrogenic systemic fibrosis can mimic systemic sclerosis or scleromyxedema (see Chapter 142).³⁰ It is seen only in individuals with significant CKD and is characterized by thickening and hardening of the skin and marked expansion and fibrosis of the dermis. Originally called nephrogenic fibrosing dermopathy, the name was changed because the pathologic

findings are not limited to the skin.³¹ Although the cause of nephrogenic systemic fibrosis remains unclear, there appears to be a high association with gadolinium, which is used as a contrast agent in magnetic resonance imaging and MRA. It is hypothesized that individuals with marked azotemia cannot eliminate the free gadolinium, which is highly toxic and results in tissue damage.³² Clinically, nephrogenic systemic fibrosis is characterized by skin involvement with or without systemic involvement.

Amyloidosis

Secondary amyloidosis, caused by the deposition of amyloid A (AA), tends to occur in concert with inflammatory rheumatologic conditions,²⁷ including rheumatoid arthritis, juvenile idiopathic arthritis, ankylosing spondylitis, psoriatic arthritis, and familial Mediterranean fever (see Chapter 168). It is almost unknown in patients with SLE, in which only a handful of cases have been reported. This probably arises from the fact that patients with lupus have no increase in serum AA proteins during inflammatory episodes.

Clinically, renal amyloidosis is manifested as nephrotic syndrome and progressive renal failure. On imaging, the kidneys tend to be larger than expected because of amyloid deposition. On LM, amyloid fibrils are seen deposited within the mesangial regions and demonstrate dichroic birefringence under polarized light in tissue stained with Congo red. Amyloid can also infiltrate the tubulointerstitial compartment and lead to renal tubular defects.

In familial Mediterranean fever there is evidence that colchicine therapy may prevent the appearance of proteinuria and renal damage.³³

Gout

In the majority of cases, gout results from diminished kidney tubular secretion of uric acid. A number of pharmacologic agents can alter tubular function and result in hyperuricemia, such as cyclosporine, diuretics, and low-dose salicylates. Chronic hyperuricemia may involve the kidney in two distinct forms: chronic urate nephropathy and uric acid nephrolithiasis.

Before effective antihyperuricemic treatment, the prevalence of uric acid nephrolithiasis in patients with gout was about 20%.³⁴ Chronic urate nephropathy is secondary to urate deposition in the renal interstitium, which results in a chronic inflammatory reaction and varying degrees of fibrosis (tubulointerstitial disease). Clinically, this can be manifested as mild proteinuria, concentrating deficits, and potentially CKD. As opposed to chronic urate nephropathy, which occurs in patients with gout, acute uric acid nephropathy tends to occur in patients with bulky cancers in whom tumor lysis syndrome develops. It is characterized by oliguric AKI secondary to precipitation of uric acid crystals within the tubules. Classic measures used to prevent tumor lysis syndrome have included the use of allopurinol, alkalization of urine, and aggressive volume expansion. Newer medications, such as uricase (Rasburicase), catalyze uric acid into allantoin, which is more readily excreted by the kidney and may thereby decrease the incidence of tumor lysis syndrome.

The presence of gout in concert with CKD warrants consideration of the following potential underlying disorders:

- Familial juvenile hyperuricemia
- Chronic lead intoxication
- Deficiency of hypoxanthine-guanine phosphoribosyltransferase (HPRT)

Familial juvenile hyperuricemia is an autosomal dominant disorder localized to chromosome 16³⁵ and is characterized by severe underexcretion of filtered urate and renal failure. The renal failure results from tubulointerstitial disease, but this does not appear to be due to urate deposition. Early treatment with allopurinol may improve the kidney prognosis.³⁶

Chronic lead intoxication leads to tubulointerstitial damage with resultant impairment of tubular function. It can be manifested clinically as saturnine gout as a result of decreased urate secretion,³⁷ renal glucosuria, or aminoaciduria. Continued lead exposure produces progressive tubular atrophy and fibrosis, hypertension, and a decline in kidney function. Therefore, occult chronic lead exposure should be suspected when the constellation of hypertension, gout, and CKD is uncovered.

HPRT deficiency is an X-linked disorder. Deficiencies of HPRT lead to an inability to recycle hypoxanthine and guanine and result in the overproduction of uric acid. Clinically, its most severe form is known as Lesch-Nyhan syndrome, which is characterized by mental retardation, choreoathetosis, and self-mutilating behavior with signs of gouty arthritis and uric acid stone disease. Less severe forms of HPRT deficiency may appear as early-onset gout and sometimes have a positive family history.

Renal lesions with other rheumatic diseases

Poststreptococcal GN rarely develops in individuals who contract acute rheumatic fever because the nephritogenic and rheumatogenic strains of β -hemolytic streptococci are different. However, cases of mesangial proliferative GN have been described.³⁸

Persistent mesangial proliferative GN, manifested clinically as non-nephrotic-range proteinuria associated with microscopic hematuria, sometimes develops in patients with polymyositis and dermatomyositis.

A variety of renal abnormalities have been described in patients with psoriatic arthritis, including secondary amyloid and membranous GN.³⁹

Common renal manifestations of sarcoidosis include hypercalcemia-associated nephrolithiasis and interstitial nephritis with granuloma formation.⁴⁰ Infrequently, sarcoidosis may be manifested as obstructive uropathy secondary to retroperitoneal lymph node involvement. TINU syndrome is relatively uncommon and is characterized by eye pain associated with renal failure in young women.⁴¹ The differential diagnosis for interstitial nephritis associated with ocular findings should also include a number of rheumatologic disorders: sarcoidosis, ANCA-associated granulomatous vasculitis, SLE, Sjögren syndrome, and Behçet disease.

RENAL COMPLICATIONS OF DRUGS USED IN RHEUMATOLOGY

Rheumatologists are well aware of the potential nephrotoxicity of the medications that they prescribe. In addition, many over-the-counter nonprescription drugs have significant potential for adversely affecting kidney function. It is estimated that on any given day, one in five adults uses an analgesic medication. Use of such drugs is even more prevalent in patients with rheumatologic disorders, and many use them without informing their doctor. Therefore, periodic assessment of kidney function is warranted.

Nonsteroidal antiinflammatory drugs

Traditional NSAIDs inhibit both isoforms of the cyclooxygenase (COX) enzyme (COX-1 and COX-2), thereby impairing the production of prostaglandins (PGE₂), prostacyclin (PGI₂), and thromboxanes.

By focusing on inhibition of COX-2 to maintain antiinflammatory efficiency but avoiding inhibition of COX-1, there was also the consideration that these drugs might be more sparing of the kidneys. However, clinical models have demonstrated that COX-2 is probably the key sodium-regulating enzyme within the salt-handling parts of the kidney. A meta-analysis examining 19 randomized trials using COX-2 inhibitors demonstrated that they increased systolic blood pressure when compared with placebo and traditional NSAIDs.⁴² Additionally, selective COX-2 inhibitors induce reversible reductions in the GFR similar to that seen with traditional NSAIDs. As with nonselective NSAIDs, these effects are rarely of clinical significance unless they occur in a patient with compromised kidney function. Based on these data, one can assume that all NSAIDs, whether traditional or COX-2 selective, have a dose-dependent effect on blood pressure.

Functional effects

Reduction in glomerular filtration rate

The most common renal side effect of NSAIDs is a functional reduction in the GFR. Clinically, this is manifested as a clinical spectrum of mild azotemia to frank oliguric AKI. Typically, the azotemia is reversible once use of the NSAID is discontinued. Unfortunately, the functional azotemia may progress to acute tubular necrosis, which may take weeks to resolve or, on rare occasion, can result in permanent kidney failure. The risk for AKI from NSAIDs is dose dependent and most often manifested within the first few weeks.⁴³

The major risk for the development of functional azotemia with NSAID use is preexisting kidney disease or use in combination with other nephrotoxic agents. Additionally, NSAIDs are relatively contraindicated in settings of preexisting renal hypoperfusion that occur with effective intravascular volume depletion, either absolute or relative, such as nephrotic syndrome, congestive heart failure, cirrhosis, and protein-wasting enteropathies. Finally, because of progressive CKD with aging, one should prescribe NSAIDs judiciously in the elderly. Renal function should be monitored closely in high-risk patients treated with NSAIDs.

Hyperkalemia

Under normal conditions, PGI₂ stimulates renin-angiotensin-aldosterone secretion. Inhibition of PGI₂ may result in severe hyperkalemia, especially in patients with underlying CKD.

Peripheral edema

Inhibition of PGE₂ results in increased sodium reabsorption, which is manifested as edema. Edema typically occurs within the first week of therapy and is associated with a 1- to 2-kg gain in weight.

Interstitial nephritis and nephrotic syndrome

Less frequent than their functional effects, NSAIDs can produce overt histologic lesions of the kidneys, specifically, allergic interstitial nephritis, minimal change disease, and probably membranous nephropathy.⁴⁴

Allergic interstitial nephritis

Allergic interstitial nephritis occurs as an idiosyncratic reaction to NSAIDs and was commonly associated with fenoprofen use. Clinically, patients have AKI associated with mild proteinuria, usually less than 1 g/day. Rash, eosinophilia, and other systemic features are generally absent.

Nephrotic syndrome

NSAID-induced minimal change disease is typically manifested as anasarca and nephrotic-range proteinuria associated with tubulointerstitial nephritis.⁴⁵ Membranous nephritis is also manifested as massive proteinuria.⁴⁴ Kidney biopsy is needed to distinguish between these two histologic lesions because both are associated with nephrotic syndrome.

Analgesic nephropathy and papillary necrosis

Analgesic nephropathy is characterized by renal papillary necrosis and chronic interstitial nephritis caused by prolonged and excessive consumption of combination analgesics, typically those containing phenacetin. Analgesic nephropathy is manifested as patchy interstitial ischemia and fibrosis in the renal medulla.

Chronic use of NSAIDs is generally safe. However, daily NSAID use for more than 1 year may be associated with an increased risk for CKD, perhaps secondary to papillary necrosis. In the setting of AKI, NSAID therapy should be discontinued immediately. The hemodynamically mediated alterations typically improve relatively quickly, but NSAID-related glomerulopathy and CKD may persist after discontinuation of the offending agent.

Calcineurin inhibitors: cyclosporine and tacrolimus**Acute kidney injury**

Cyclosporine is associated with both acute and chronic renal toxicity.⁴⁶ The other major calcineurin inhibitor, tacrolimus (FK506), has the same potential for nephrotoxicity as cyclosporine does.⁴⁷ Both agents cause dose-dependent renal afferent artery vasoconstriction with subsequent acute decreases in the GFR.

Hypertension

Both calcineurin inhibitors can induce hypertension through a variety of mechanisms, including acting as powerful vasoconstrictors of the preglomerular vasculature and enhancing vascular responsiveness to vasopressin and angiotensin, as well as other mechanisms of action.

Chronic kidney disease

The long-term nephrotoxicity of calcineurin inhibitors appears to be dependent on both time and dose, results from interstitial fibrosis, and tends to be irreversible. This chronic nephrotoxicity is well documented in patients with rheumatoid arthritis.⁴⁷

Hemolytic-uremic syndrome

Though an infrequent complication, both calcineurin inhibitors have been implicated in causing hemolytic-uremic syndrome or a microangiopathic syndrome.

Hyperuricemia

Cyclosporine causes hyperuricemia and may lead to gout in individuals both with and without an organ transplant.⁴⁸ The afferent artery constriction from cyclosporine results in increased proximal tubular uric acid absorption and hyperuricemia. Calcium channel blockers such as amlodipine significantly reduce the hyperuricemia associated with cyclosporine use. Uricosuric agents or allopurinol may be beneficial.

RHEUMATOLOGIC COMPLICATIONS OF KIDNEY DISEASE

Most disorders of the soft tissues, joints, and bones that are referable to kidney disease occur in the setting of a diminished GFR, that is, with

CKD or in the post-kidney transplant setting. The cause of most can be traced to the biochemical imbalances classically associated with kidney failure, including disturbances in calcium and phosphorus homeostasis as a result of alterations in the vitamin D and parathyroid hormone (PTH) axes and retention of uremic toxins, such as β_2 -microglobulin. An exception to this rule is the syndrome of hereditary hypophosphatemic rickets, in which the GFR is normal but there is excessive renal tubular wasting of phosphorus.

Rheumatologic complications in patients with ESRD are very common, with more than 70% having joint pain. Additionally, a temporal relationship is seen between the duration of kidney disease and the prevalence of rheumatologic conditions.

Etiologic factors specific to kidney failure and their associated rheumatic syndromes **β_2 -Microglobulin amyloidosis**

β_2 -Microglobulin is an 11.8-kDa protein that is a component of the major histocompatibility complex type I antigen. It is normally filtered by the glomerulus and reabsorbed and catabolized by renal tubular cells. In ESRD, production exceeds excretion, which can result in a 60-fold increase in plasma β_2 -microglobulin concentration. The β_2 -microglobulin protein then appears to be modified by 3-deoxyglucose to form a glycosylated protein, which resists further catabolism and is found in amyloid deposits.⁴⁹

β_2 -Microglobulin has a high affinity for collagen, which may explain its predilection for deposition in bones, joints, and synovium. An autopsy study demonstrated a direct correlation of amyloid deposition with the number of years of dialysis.⁵⁰

Clinical features of β_2 -microglobulin amyloidosis include carpal tunnel syndrome, a destructive spondyloarthritis, bone cysts and fractures as a result of β_2 -microglobulin amyloid, and shoulder pain secondary to periarticular deposits of β_2 -microglobulin in the joint capsule, along with joint tenderness and loss of mobility (see Chapter 168). Similarly, adhesions caused by deposition of β_2 -microglobulin in the flexor tendons of the hand can result in contractures and thickening. Joint effusions are common with periarticular deposition of β_2 -microglobulin, especially in the shoulders and knees. See Chapter 168 for more details on this syndrome.

Calcium, phosphorus, and parathyroid hormone derangements

As the GFR declines, the filtered load of phosphate decreases, thereby leading to a positive phosphate balance. This can be seen in as early as stage 2 CKD (see Table 38.2). Phosphate retention increases as the GFR declines. Prolonged hyperphosphatemia can lead to soft tissue and vascular calcifications related to an increase in the calcium-phosphate product.⁵¹ An elevated calcium-phosphorus product is associated with increased morbidity and mortality.

Patients with CKD also often suffer from hypocalcemia. The etiology of the hypocalcemia is multifactorial and related to decreased production of 1,25-dihydroxyvitamin D, as well as to diffuse deposition of calcium (see later) as a result of increased calcium-phosphate product. The combination of hypocalcemia, reduced synthesis of 1,25-dihydroxyvitamin D, and hyperphosphatemia results in parathyroid gland proliferation with subsequent secondary hyperparathyroidism.

Strategies aimed at reducing hyperphosphatemia may ameliorate the development of secondary hyperparathyroidism. The serum phosphorus concentration should be maintained between 2.7 and 4.6 mg/dL, primarily through restriction of dietary phosphorus to between 800 and 1000 mg/day. However, because dietary phosphorus restrictions are often not sufficient, oral phosphate binders are needed. In the past, aluminum-based phosphate binders were used commonly, but this led to significant toxicity, including aluminum-related bone disease. Now, the most commonly used phosphate binders are calcium-based phosphate binders (calcium acetate) and phosphate-binding resin (sevelamer).

Oxalate deposition

Urinary excretion of oxalate is markedly impaired once the GFR is reduced below 20 mL/min (stage 4 CKD). Secondary oxalosis caused by CKD shares many features with the primary genetic form of hyperoxaluria, including increased vascular and osteoarticular calcification secondary to deposition of the poorly soluble calcium-oxalate complex. Avoiding carrots, spinach, cocoa, peanut butter, nuts, chocolate, megadose vitamin C, and tea will reduce dietary oxalate. Oral phosphate binders will also bind to oxalate and decrease its serum level.

Crystal arthropathies

Gout

With CKD, gout is paradoxically uncommon, in part because the fractional excretion of urate rises steadily as the GFR falls. Nevertheless, hyperuricemia is the rule in advanced CKD, which suggests that the uremic milieu suppresses the acute inflammatory response to urate crystals. An acute gout attack in patients with CKD should be treated with either intraarticular or systemic corticosteroids, depending on the number of joints involved. Colchicine is relatively contraindicated in patients in the later stages of CKD. Additionally, the use of NSAIDs may precipitate either hemodynamically mediated or tubulointerstitial AKI and should therefore be avoided in patients with CKD.

Long-term management of chronic gout with allopurinol requires dose adjustment for the diminished GFR in patients with CKD, but the dose of allopurinol should be sufficient to lower the uric acid level. The uricosuric agents sulfinpyrazone and probenecid are ineffective when the GFR is lower than 30 mL/min.

Calcium pyrophosphate dihydrate deposition disease

In patients with CKD, calcium pyrophosphate dihydrate deposition disease is more common than gout. Treatment of the acute arthritis is best accomplished with intraarticular injections; NSAIDs are relatively contraindicated.

Hydroxyapatite arthropathy

Acute episodes of joint pain, particularly in the shoulders, can punctuate the more chronic course of periartropathy because of calcium hydroxyapatite deposits. Seen in patients with ESRD, it is strongly correlated with prolonged hyperphosphatemia and an elevated calcium-phosphorus product. Crystals are usually absent on synovial fluid examination. Periarticular deposits may become large complex masses, called tumoral calcinosis.

The aims of therapy are threefold: (1) reduction of acute inflammation with intraarticular injections and cautious use of antiinflammatory drugs, (2) joint rest, and (3) reduction in calcium-phosphorus product by increasing phosphate binders and stopping vitamin D analogue administration.

Oxalate arthropathy

Arthritis associated with articular and periarticular deposits of calcium oxalate occurs secondary to CKD. Oxalate crystals are deposited in the renal parenchyma, skin, bone, and blood vessels and in and around joints. There they cause chondrocalcinosis, synovial calcification, and chronic or acute arthropathy.

Clinical features of renal bone disease

Renal osteodystrophy

Renal osteodystrophy is a term used to describe the skeletal complications of ESRD caused by a complex amalgam of various pathologic processes (see Chapter 205). The four principal types are osteitis fibrosa (formally known as osteitis fibrosa cystica), osteomalacia, adynamic bone disease, and mixed disease. Mixed osteodystrophy is an amalgam of osteitis fibrosa and osteomalacia (see later).

The classic histologic form of renal osteodystrophy is osteitis fibrosa, a lesion directly attributable to the secondary hyperparathyroidism seen with CKD. The hallmark lesion is peritrabecular fibrosis in the setting of accelerated bone resorption and formation. Clinically, it can be manifested as bone tenderness and proximal muscle weakness. Radiographic findings include subperiosteal bone resorption, best observed in the middle phalanges, and osteosclerosis.

Osteomalacia, as opposed to osteitis fibrosa, is characterized by a reduced rate of bone turnover associated with increased osteoid volume and defective mineralization. Because osteomalacia is associated with aluminum intoxication, its incidence is decreasing. Clinically, osteomalacia tends to cause more severe bone pain than osteitis fibrosa does and is also associated with pathologic fractures. Osteomalacia tends to have minimal radiographic

findings but may be associated with pseudofractures, which are radiolucent bands that run perpendicular to the long axis of bones.

Adynamic bone disease, also known as aplastic bone disease, is now the most common type of renal osteodystrophy. The pathogenesis of this condition is poorly understood, but a key factor appears to be excessive suppression of PTH. Bone turnover is markedly decreased, but unlike osteomalacia, osteoid formation is not increased. Clinically, adynamic bone disease may be asymptomatic or be manifested as hypercalcemia or an increased risk for hip fractures.⁵²

Management is based on the type of renal osteodystrophy. Although tests of PTH and serum aluminum levels may suggest the underlying pathologic process, the diagnostic gold standard is dual-labeled bone biopsy. General management should include normalization of serum phosphorus levels; correction of acidemia; avoidance of prolonged use of aluminum-containing phosphate binders, including sucralate; and control of hyperparathyroidism with the judicious use of vitamin D analogues. Despite effective therapy, intractable hyperparathyroidism may require parathyroidectomy.

"Brown tumors"

Severe hyperparathyroidism may lead to the development of osteoclastomas, also known as "brown tumors." They typically occur at the medial end of the clavicle but can form anywhere in the calvaria, long bones, sternum, or spine.

Other arthropathies in dialysis patients

Typical erosive osteoarthritis, mainly of the interphalangeal joints, is common in individuals maintained on dialysis. The clinical and radiologic features are indistinguishable from those of individuals without CKD. As in the general population, there is a female preponderance and an increased incidence with age. However, erosive osteoarthritis appears to be more common in patients with ESRD.⁵³ This increased incidence may be related to a higher incidence of hyperparathyroidism or iron overload (or both).

Tendinitis occurs frequently in patients undergoing hemodialysis; hyperparathyroidism appears to be the predisposing factor. Tendon rupture is common, principally of the quadriceps tendon but also the patellar, Achilles, triceps, or finger extensor tendons. The differential diagnosis of generalized muscle weakness in a patient maintained on dialysis is extensive and includes life-threatening processes such as severe hyperkalemia, severe hypophosphatemia, and bacteremia. More chronic or progressive weakness, if not neuropathic in origin, suggests a possible myopathy⁵⁴ that may be due to vitamin D deficiency, possible aluminum toxicity (see earlier), progressive malnourishment, or hyperparathyroidism.

Lupus tends to become more quiescent with the development of ESRD, although symptoms may continue.⁵⁵ Additionally, patients with rheumatoid arthritis may continue to have arthritis while undergoing hemodialysis. Individuals on dialysis who have previously received extended courses of corticosteroids for lupus or similar rheumatic conditions are at particular risk for hip osteonecrosis.

Arthropathies in renal transplant patients

Gout

Gout is just one of several arthropathies that are prevalent in kidney transplant recipients. The incidence of gout is increased in individuals who have received a kidney transplant and are treated with cyclosporine.

Osteopenia after transplantation

Before kidney transplantation, patients with CKD often have low bone mineral density because of renal osteodystrophy. After renal transplantation there is a rapid decline in bone mineral density. This rapid decline is due primarily to the use of glucocorticoids and persistent hyperparathyroidism. Clinically, the incidence of fractures is increased within the first 6 months after transplantation.⁵⁶ Bone loss may be reduced by the use of corticosteroid-free or ultralow-dose corticosteroid regimens. Additionally, the use of calcium, vitamin D, and bisphosphonates should be considered in all recipients of kidney transplants.

The nervous system in rheumatic disease

■ JULIUS BIRNBAUM

- A wide spectrum of central nervous system and peripheral nervous system syndromes is associated with different systemic rheumatic diseases.
- An appropriate diagnostic framework can help the clinician distinguish whether neurologic syndromes are attributable to a rheumatic disease or to an alternative cause.
- Distinguishing whether neurologic syndromes stem from rheumatic diseases versus noninflammatory etiologies can help in the decision whether to implement symptomatic or immunosuppressive strategies.
- Although the American College of Rheumatology nomenclature and case definitions for neuropsychiatric systemic lupus erythematosus (SLE) are a useful tool, recent studies regarding the frequency of individual neurologic syndromes in SLE patients suggest that these case definitions may need to be modified.
- Demyelinating syndromes that occur in patients with SLE or Sjögren syndrome can be distinguished from multiple sclerosis or another idiopathic demyelinating syndrome.

INTRODUCTION

The interface between neurology and rheumatology includes a fascinating spectrum of syndromes that can affect any region in the central nervous system (CNS) and the peripheral nervous system (PNS). Syndromes may be seen ubiquitously across rheumatic diseases (e.g., a mononeuritis multiplex) or may be associated with only a single disease. Some neurologic disorders may reflect ominously escalating disease activity and require quick institution of immunosuppressive therapy. However, other neurologic syndromes may stem entirely from causes other than rheumatic diseases for which immunosuppressive therapy is contraindicated. Therefore the clinician needs to consider carefully other vascular, infectious, traumatic, metabolic, and neoplastic causes of neurologic syndromes.

On one level, this chapter is devoted to the neurologic complications of rheumatic diseases, with a focus on the spectrum of neurologic syndromes seen in individual rheumatic disorders as well as across many rheumatic diseases. However, this chapter also introduces the paradigm of using phenotypes of neurologic disease as a tool for identifying immunopathogenic mechanisms, and to better understanding when to apply immunosuppressive versus symptomatic therapies.¹ The reader is referred to other chapters in this book for a discussion of neurologic manifestations of antiphospholipid syndrome (Chapter 139), inflammatory myopathies (Chapter 149), and CNS vasculitis (Chapter 164). The neurologic complications of the remaining rheumatic diseases are addressed in this chapter.

EVALUATION OF THE PERIPHERAL NEUROPATHIES IN SYSTEMIC RHEUMATIC DISEASES

Classification and initial diagnostic approach to peripheral neuropathies

The classification, spectrum, clinical features, and initial diagnostic evaluation of neuropathies in rheumatic diseases are considered in [Figure 39.1](#). The most common neuropathies reported across the spectrum of rheumatic diseases are axonal sensory/sensorimotor polyneuropathies. Such symmetric

polyneuropathies occur mainly in the distal feet, are associated with lower rheumatic disease activity, are indolently progressive, and rarely require the use of immunosuppressive strategies. The evaluation of potential neuropathies should include electrodiagnostic studies, which can distinguish between axonal and demyelinating neuropathies and can help uncover asymmetric features that might suggest either a radiculopathy or a mononeuritis multiplex (see later in this chapter).

In contrast, there is a subset of painful sensory neuropathies may cause burning pain but may be associated with normal electrodiagnostic studies. Such neuropathies are designated as “small-fiber” neuropathies, target thinly myelinated A-delta and unmyelinated C-fiber nerves, and can be associated with selective deficits to “small-fiber” modalities (i.e., pinprick and temperature). Given that the integrity of such unmyelinated nerves cannot be assessed by electrodiagnostic studies, other diagnostic approaches such as skin biopsy or quantitative sensory testing are required.

Nerve and muscle biopsy is primarily reserved for patients in whom there is clinical or electrophysiologic suspicion of mononeuritis multiplex (see later in this chapter). Neuropathies can occur due to competing comorbidities rather than rheumatic diseases, and a strategy for memorizing most of the differential diagnoses is shown in [Box 39.1](#). The diagnostic approach to vasculitic neuropathies now represents a suitable starting point to focus on the specific PNS manifestations of rheumatic diseases.

PERIPHERAL NERVOUS SYSTEM MANIFESTATIONS OF VASCULITIS

Presentations of vasculitic neuropathies

Mononeuritis multiplex

Mononeuritis multiplex (also termed *multiple mononeuropathy*) has been described as one of the most dramatic disorders in clinical medicine because the presentation and evolution of this neuropathy can be stark and fulminant.^{1,2} When it occurs with such an explosive tempo, multiple named nerves are affected and can be remembered using the following three As: Acuity, Asymmetry, and Asynchrony. However, mononeuritis multiplex can also develop more gradually in a stepwise pattern that manifests over weeks or even over months.

Mononeuritis multiplex is necessarily a sensory neuropathy, which is usually painful. The absence of pain is a clinical red flag that argues against the diagnosis of mononeuritis multiplex. Sparing of sensory nerves on nerve conduction study is diagnostically incompatible with mononeuritis multiplex.

Mononeuritis multiplex is usually a length-dependent neuropathy. The longest nerves in the lower extremities are affected, including the peroneal nerve and sural nerve (more than 80% of cases), followed by the tibial nerve (38% to 50%), and then nerves in the upper extremity, including the ulnar nerve (35%), median nerve (35%), and radial nerves (25% to 40%).²

Other clinical presentations of a vasculitic neuropathy

Symmetric sensory or sensorimotor polyneuropathies may occur in some vasculitides at a frequency similar to that of mononeuritis multiplex. Small-fiber neuropathies are infrequently described but likely underdiagnosed.

Diagnosis

Electrodiagnostic studies

Nerve-conduction studies (NCS) are an essential part of the diagnostic workup of potential mononeuritis multiplex. First, such studies can confirm

peripheral neuropathies are increased compared with giant cell arteritis, Behçet syndrome, and other vasculitides. The frequency of vasculitic neuropathies is higher in Churg-Strauss syndrome than in other ANCA-associated vasculitides, which may reflect the fact that peripheral nerve injury in Churg-Strauss syndrome occurs due to eosinophilic infiltration as well as ischemic disease.

The wide range of prevalences of neuropathies reported in specific vasculitides reflects differences in how neuropathies were ascertained (clinically, electrophysiologically, and/or through tissue biopsies) and whether cohorts were composed of unselected patients or highly select patients studied at tertiary care neuromuscular centers.

Importance of evaluating for infection in patients with granulomatosis with polyangiitis (formerly known as Wegener granulomatosis) and Churg-Strauss syndrome

Cranial neuropathies may reflect regional granulomatous disease in the retro-orbital region (e.g., an orbital pseudotumor syndrome), in the cavernous sinus, at the base of the meninges (e.g., basilar meningitis), or in the arachnoid and pial meningeal layers (e.g., leptomeningitis).⁴ But in all systemic vasculitides and rheumatic diseases, such syndromes can also represent skull-based, meningeal, and/or parenchymal extension of opportunistic infections. Therefore rapid evolution of ophthalmoparesis, facial numbness, or lower cranial nerve deficits (which may suggest a basilar meningitis) should prompt emergent neuroimaging, ideally by magnetic resonance imaging (MRI); a spinal tap if there is suspicion of a meningeal process; and consultation with a neurologist.

Other cranial neuropathies can occur due to vasculitic mechanisms as opposed to space-occupying disease. Such neuropathies include trigeminal neuropathies and facial neuropathies (unilateral more than bilateral). Hearing loss in a patient can be conductive (e.g., due to granulomatous disease causing bony or cartilaginous destruction), sensorineural, or mixed.

Treatment of vasculitic neuropathies

Treatment of mononeuritis multiplex should reflect the disease-specific strategies used when other vital end organs are jeopardized (e.g., a pulmonary-renal syndrome). See Chapters 155 and 157 on polyarteritis nodosa and ANCA-associated vasculitis for a discussion of protocols used for induction and maintenance of remission. In general, treatment of mononeuritis multiplex invariably uses regimens that induce remission in other vital organs. Studies have suggested that rituximab may have equivalent efficacy to cyclophosphamide in inducing disease remission in the ANCA-associated vasculitides.⁷ Oral or intravenous regimens of cyclophosphamide can be used in other systemic vasculitides. There is also ongoing interest in evaluating the efficacy of rituximab for the treatment of vasculitic neuropathies in cryoglobulinemias and Sjögren syndrome, which may be mediated by direct antibody damage, immune-complex deposition, and exuberant B-cell hyperreactivity.

Although immunosuppressive therapy is uniformly required in patients with the asymmetric presentation of mononeuritis multiplex, symmetric polyneuropathies may be more indolently progressive, can be clinically restricted to distal regions, and may cause primarily sensory as opposed to motor deficits. The decision about initiating immunosuppressive therapy may be guided by whether there is background disease activity or concomitant involvement of other end organs. However, such symmetric polyneuropathies may be caused by corticosteroid-induced diabetes or by other mechanisms associated with cumulative disease damage. In such cases, symptomatic as opposed to immunosuppressive therapy may be warranted.

PERIPHERAL NERVOUS SYSTEM MANIFESTATIONS OF SJÖGREN SYNDROME

Patients with Sjögren syndrome (see also Chapter 138) can be affected by a wide spectrum of most of the neuropathies which are noted in Figure 39.1. This includes axonal neuropathies (e.g., symmetric axonal sensory/sensorimotor polyneuropathies as well as vasculitic neuropathies), small-fiber neuropathies, other sensory neuropathies such as neuronopathies, autonomic neuropathies, and sensory and motor cranial neuropathies.¹

It may initially be difficult to approach the classification of such neuropathies in a systematic fashion, to understand whether a given neuropathy is typical or unusual in an individual patient with Sjögren syndrome, to assess the relationship of neuropathies to different etiopathogenic pathways, and finally to use an understanding about frequency, classification, and

etiopathogenesis to devise an effective therapeutic plan. These issues are therefore described in what follows.

Classification of peripheral neuropathies in Sjögren syndrome

Axonal neuropathies

Axonal polyneuropathies are reported in 1% to 10% of patients with Sjögren syndrome.^{1,8} These neuropathies are usually symmetric, are sensory or sensorimotor, typically manifest with length-dependent sensory symptoms, have minimal to absent weakness, are insidiously progressive, and rarely require immunosuppressive therapy.

The presentation of asymmetric mononeuritis multiplex is decidedly less common, seen in fewer than 1% of Sjögren syndrome patients, but it can lead to severe weakness that requires immunosuppressive therapy. The presentation, diagnosis, and evaluation of mononeuritis multiplex in Sjögren syndrome is similar to that described in the previous discussion of vasculitic neuropathies.

Mononeuritis multiplex can be associated with stigmata of cutaneous vasculitis, clinical and serologic indicators of higher disease activity, including cryoglobulinemia and C4 hypocomplementemia.

Sensory neuronopathies

Although occurring in fewer than 1% of Sjögren syndrome patients, the sensory neuronopathies (also called ganglionopathies) are devastating sensory neuropathies. There is loss of position sense that can affect larger joints. Such functional “deafferentation” of limbs potentially robs patients of the ability to ambulate, even when strength is preserved.⁹ Nerve-conduction studies reveal loss of multiple sensory nerve action potentials with minimal involvement of motor nerves.

Small-fiber neuropathies

Small-fiber neuropathies have been extensively reported in Sjögren syndrome patients but have not been well characterized in unselected cohorts.^{9a} Therefore, although the prevalence of such small-fiber neuropathies is difficult to ascertain, clinicians will readily appreciate that Sjögren syndrome patients frequently report burning pain and other somatosensory features described in small-fiber neuropathies. Altogether, such small-fiber neuropathies may be more prevalent than axonal neuropathies.⁸ The future characterization of small-fiber neuropathies by skin biopsy findings and other diagnostic biomarkers will clarify the frequency and mechanisms of small-fiber neuropathy in Sjögren syndrome.

Other neuropathies

Cranial neuropathies can affect sensory nerves (especially the trigeminal nerve) more than motor nerves. Unilateral or bilateral trigeminal neuropathies are the most frequent cranial neuropathy, followed by seventh nerve palsies. Sjögren syndrome patients frequently have symptoms suggestive of dysautonomia, manifesting as orthostatic symptoms, complaints of hypohidrosis or hyperhidrosis, decreased or increased gastric motility, and difficulty urinating. Formal diagnostic evaluation for autonomic neuropathies is limited to specialized centers, and therapy is mainly supportive, as has been described.¹ Plexopathies and demyelinating neuropathies are uncommon and occur in fewer than 1% of Sjögren syndrome patients.

Diagnostic evaluation, etiopathogenic relationship, and therapeutic options

The diagnostic evaluation should proceed as illustrated in Figure 39.1, using electrodiagnostic studies to help exclude a radiculopathy and to further characterize axonal neuropathies as a result of axonal and/or demyelinating disease, and skin biopsy to evaluate for potential small-fiber neuropathies. In general, mononeuritis multiplex may reflect mechanisms of immune-complex deposition, is associated with high disease activity, and requires immunosuppressive therapy. The distal axonal polyneuropathies are associated with lower disease activity and are usually managed symptomatically. The relationship of small-fiber neuropathy to disease activity requires further evaluation. Intravenous immunoglobulin has been reported to be efficacious in case series of patients with small-fiber neuropathy who have severe pain refractory to other immunosuppressive strategies¹⁰ and has been reported to halt further proprioceptive impairment in patients with sensory neuronopathies.¹

Irrespective of the use of immunosuppressive therapies, most neuropathies are painful and require separate treatment for neuropathic pain. The tricyclic antidepressants are avoided given their anticholinergic adverse effects, which can exacerbate sicca manifestations. Other therapies include

antiepileptic agents and the serotonin-norepinephrine reuptake inhibitors, which can also be effective in patients with fibromyalgia-type pain. However, Sjögren syndrome patients are more likely to develop adverse effects such as fatigue and cognitive slowing. Strategies may include slower titration toward therapeutic doses, combination of agents to induce therapeutic synergy, and a low threshold for referral to a neurologist or other pain specialist.

PERIPHERAL NERVOUS SYSTEM MANIFESTATIONS OF RHEUMATOID ARTHRITIS

As with other extraarticular complications of rheumatoid arthritis (RA), earlier and more aggressive treatment of RA has resulted in a decreased prevalence of neurologic complications that may be a result of disease activity (see Fig. 39.1). For example, mononeuritis multiplex is among the least frequent neuropathies encountered in RA patients, is associated with high disease activity, and requires immunosuppressive therapy. In contrast, distal axonal sensory or sensorimotor polyneuropathies have been reported more frequently (up to 10% of RA patients), are associated with lower disease activity, have an excellent prognosis, and can be managed symptomatically.

Compressive neuropathies are the most common neuropathies, described in 20% to 70% of patients.¹¹ Carpal tunnel syndrome (affecting the median nerve) and tarsal tunnel syndrome (affecting the posterior tibial nerve) are the most common compressive neuropathies, respectively presenting as numbness in the first three digits of the hands and feet. Compression neuropathies may result from synovial or bursa inflammation or can occur due to joint deformities or posttraumatic fibrosis not stemming from active disease. Conservative strategies, including splinting and tendon sheath injections, are tried before surgical release.

In contrast to compressive neuropathies, inflammatory demyelinating neuropathies have been temporally associated with the use of tumor necrosis factor (TNF) inhibitors.^{11a} Despite the rarity of these inflammatory demyelinating neuropathies (described in fewer than 100 RA patients treated with TNF inhibitors), such demyelinating neuropathies are otherwise not seen in RA patients, and therefore an etiopathogenic relationship is suggested. Although some patients show improvement or stabilization when the offending TNF inhibitors are withdrawn, other patients require treatment with intravenous immunoglobulin or other therapies used in the treatment of primary demyelinating neuropathies.

PERIPHERAL NERVOUS SYSTEM MANIFESTATIONS OF OTHER RHEUMATIC DISEASES

The most frequent neuropathies in patients with scleroderma and mixed connective tissue disease are entrapment neuropathies (usually at the wrist), followed by trigeminal neuropathies, which can be bilateral and occur in up to 5% of patients.¹² Axonal neuropathies have been infrequently described only in isolated case series or case reports, and require only symptomatic therapies. Gastrointestinal dysmotility may in part reflect an autonomic neuropathy.

NEUROPSYCHIATRIC SYSTEMIC LUPUS ERYTHEMATOSUS

Spectrum and attribution of neurologic syndromes: challenges and limitations

The neuropsychiatric manifestations of systemic lupus erythematosus (NPSLE) (see also Chapter 135) represent a logical and opportune disease to bridge the discussion between the PNS and CNS manifestations of rheumatic diseases. There are similar themes that are shared between PNS and CNS syndromes seen in SLE.

First, more so than patients with any other rheumatic syndrome, SLE patients show a unique predilection for developing either CNS or PNS neurologic disease attributable to causes other than primary rheumatic diseases. For example, between 40% and 50% of neurologic syndromes occurring in SLE patients may be attributable to non-SLE causes.^{13,14} Unlike patients with Sjögren syndrome, SLE patients are more likely to be taking corticosteroids and immunosuppressive therapies and are more prone to develop CNS manifestations due to infections. *Given that infections can mimic any CNS neurologic syndrome that may otherwise be mistakenly*

attributed to SLE, infections need to be included at the top of any differential diagnosis and evaluated with an appropriate level of vigilance.

Second, the current understanding of the spectrum of NPSLE has shifted dramatically over the past 10 to 15 years. This point is illustrated in Figure 39.2. Figure 39.2a shows the individual CNS and PNS syndromes that were included in the 1999 American College of Rheumatology (ACR) nomenclature and case definitions for NPSLE.¹⁵ These ACR NPSLE case definitions include 12 CNS and 7 PNS disorders. However, since publication of these ACR NPSLE case definitions, the frequency of individual neurologic syndromes has been evaluated in several cohort studies. As discussed later, several NPSLE syndromes included in the case definitions were nonspecifically seen with similar frequency in normal control subjects. Furthermore, new insights into disease classification and etiopathogenesis have been derived from other neurologic diseases and applied to NPSLE, which suggests that the ACR NPSLE case definitions need to be revised.

Altogether, these findings suggest that although the 1999 ACR NPSLE case definitions represented a valuable starting point in establishing a uniform nomenclature, such case definitions are not entirely representative of the spectrum of NPSLE disease. Therefore Figure 39.2 includes a proposed revision to the ACR case definitions. In Figure 39.2a, the neurologic syndromes initially included in the 1999 ACR case definitions that are not included in the proposed revision are indicated in shaded boxes. In Figure 39.2b, the neurologic syndromes not included in the 1999 ACR case definitions but that are included in the proposed revision are italicized. Such proposed revisions can also be useful in the evaluation of patients with suspected NPSLE, and is further discussed later in this chapter.

Peripheral nervous system manifestations of systemic lupus erythematosus

Syndromes that are currently included in the ACR NPSLE case definitions but potentially are not part of the spectrum of NPSLE

PNS syndromes that are currently included in the ACR NPSLE case definitions but potentially do not constitute part of the spectrum of PNS NPSLE are demyelinating syndromes (including Guillain-Barré syndrome) myasthenia gravis, and plexopathies, which all have been described in fewer than 1% of patients.¹⁶ These disorders may therefore be considered as the manifestation of a secondary inflammatory syndrome and therefore potentially diagnosed and treated in the same way as in non-SLE patients.

Syndromes that are not currently included in the ACR NPSLE case definitions but are part of the spectrum of NPSLE

Syndromes that are not currently included in the ACR NPSLE case definitions but constitute part of the spectrum of PNS NPSLE include the small-fiber neuropathies.^{17,18} Neuropathies have been described in up to 14% of SLE patients. Up to 40% of SLE neuropathies are attributable to non-SLE comorbidities (see Box 39.1). However, small-fiber neuropathies have been well described in SLE patients who are part of highly select neuromuscular cohorts.

Syndromes that are currently included in the ACR NPSLE case definitions and are part of the spectrum of NPSLE

Neuropathies have been described in up to 14% of SLE patients,¹⁴ but 40% of neuropathies are attributable to associated non-SLE comorbidities (see the VITAMINS mnemonic in Box 39.1). Studies that reported a higher frequency of SLE neuropathies were published in an era in which SLE disease was not aggressively treated, were evaluated in comparatively smaller numbers of patients, or systematically screened for SLE neuropathies even in the absence of neuropathic symptoms.

As in Sjögren syndrome patients, the most common neuropathies in SLE patients are axonal sensory or sensorimotor polyneuropathies, which as indicated in Figure 39.1 may occur in 5% to 10% of patients. Cranial neuropathies and mononeuritis multiplex are seen less frequently, with both neuropathies occurring at a frequency of less than 1%. Mononeuritis multiplex is associated with highly active SLE and requires immunosuppressive therapy. Yet except in the vasculitic neuropathies, there are no SLE-specific features that are found in SLE patients with particular subtypes of neuropathies but not in SLE patients without neuropathies. Therefore, with the exception of vasculitic neuropathies, the treatment of neuropathies is guided by treatment of the underlying SLE disease. Symptomatic therapies may be appropriate for patients with distal axonal polyneuropathies if such polyneuropathies are not progressing to cause significant weakness, if the intensity and distribution of neuropathic pain is unchanged, and if such neuropathies are not associated with increasing SLE activity.

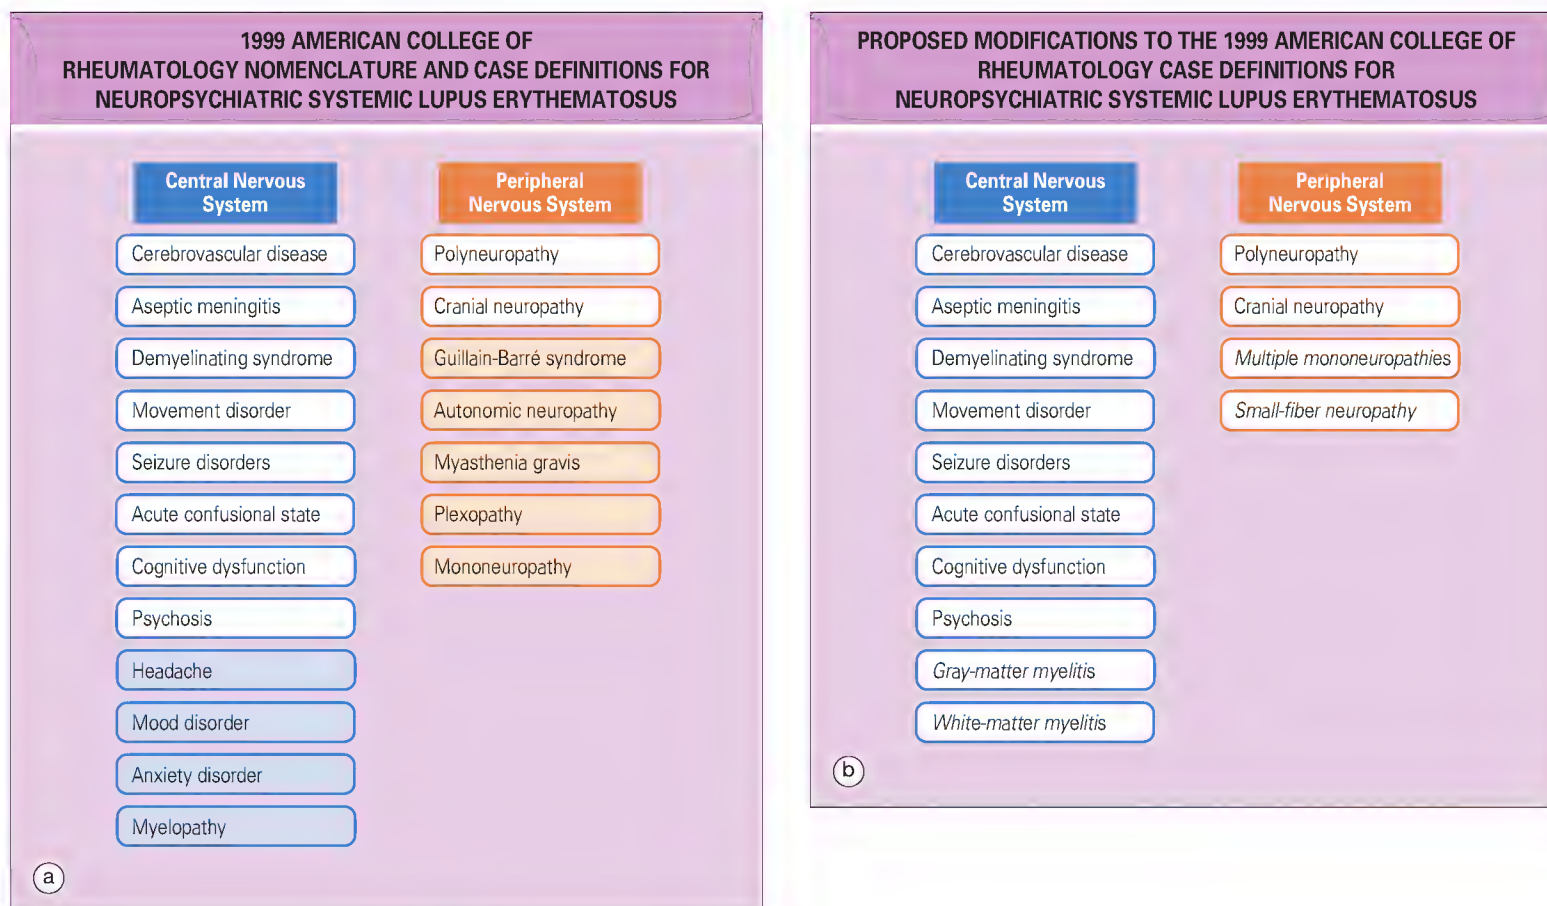

Fig. 39.2 (a) The 19 case definitions included in the 1999 American College of Rheumatology (ACR) nomenclature and case definitions for neuropsychiatric systemic lupus erythematosus (NPSLE). (b) The proposed revision to the ACR NPSLE case definitions no longer includes central nervous system syndromes that occur with similar frequency in non-SLE controls, (i.e., headache, mood disorders, and anxiety disorders) and no longer includes peripheral nervous system syndromes described in less than 1 percent of SLE patients (e.g., Guillain-Barré syndrome, autonomic neuropathies, myasthenia gravis, and plexopathies). Recent studies that have characterized subtypes of myelitis, including gray-matter and white-matter myelitis, and small-fiber neuropathies in SLE patients, are included in this proposed revision.

Central nervous system manifestations of systemic lupus erythematosus

Differential diagnosis

As with the PNS manifestations of NPSLE, up to 40% of CNS syndromes in SLE patients can be attributed to non-SLE causes.¹³ The initial approach therefore requires the development of a differential diagnosis to consider such non-SLE causes. Although such a differential diagnosis can seem challenging, it can be simplified by using the VITAMINS mnemonic in Box 39.2.

Syndromes that are included in the ACR NPSLE case definitions but may not be part of the spectrum of NPSLE

Figure 39.2 indicates those CNS syndromes that are seen in SLE patients at a frequency similar to RA patients and even in healthy controls, and may not constitute part of the spectrum of CNS NPSLE.¹⁹ Such syndromes include headaches, anxiety, and depression.

However, the ultimate decision about disease attribution requires clinical judgment. For example, there may be the infrequent SLE patient who develops a headache that shows unusual severity or intractability, may be a departure from a prior headache pattern, or manifests in the context of highly active SLE with no other non-SLE cause identified. In such exceptional cases, the headache may be considered to be attributable to SLE (i.e., a “lupus headache”), even though most SLE patients have headaches that can be managed similarly to those in non-SLE patients.

Syndromes that are not included in the ACR NPSLE criteria but likely are part of the spectrum of NPSLE

Not included in the ACR criteria but probably part of the spectrum of NPSLE are the different phenotypes of demyelinating syndromes, including gray-matter myelitis, white-matter myelitis, and neuromyelitis optica.²⁰ The approach to the demyelinating manifestations of SLE and other rheumatic diseases is considered in the final section of this chapter.

BOX 39.2 DIFFERENTIAL DIAGNOSIS OF CENTRAL NERVOUS SYSTEM MANIFESTATIONS OF SYSTEMIC LUPUS ERYTHEMATOSUS—THE MNEMONIC “VITAMINS”

Vascular

- Strokes (thrombotic and embolic)
- Strokes (hemorrhagic): subarachnoid (including aneurysm from septic emboli), subdural, or epidural
- Bland (e.g., conventional risk factors for atherosclerosis)
- Infectious (e.g., septic emboli, septic thrombophlebitis)

Infectious

- Classification as to cause (bacterial, fungal, malignancy related)
- Classification as to anatomic region
 - Parenchymal (e.g., abscess, parameningeal extension of meningitis)
 - Meningeal: meningitis
 - Vascular: septic emboli, septic thrombophlebitis

Traumatic: as in the general population (e.g., traumatic epidural hematoma)

Autoimmune: other primary autoimmune or inflammatory syndromes (e.g., sarcoidosis, demyelinating syndromes)

Metabolic: uncommon, but includes hyperhomocysteinemia (vascular), vitamin B₁₂ deficiency

Iatrogenic: steroids or glucose intolerance, infections (see above), use of nonsteroidal antiinflammatory drugs (aseptic meningitis)

Neoplastic: structural/metastatic (intraparenchymal, leptomeningeal)

Structural: as in disorders seen in the general population

Prevalence, spectrum, disease attribution, and immunologic features of CNS syndromes included in the ACR NPSLE criteria

For all of the CNS syndromes considered in the following sections, the reader is urged to use the VITAMINS mnemonic (see Box 39.2) to help discriminate between SLE and non-SLE causes.

Strokes. Cerebrovascular episodes have been described in 5% to 15% of SLE patients. Small-vessel disease causing lacunar infarcts is more common than larger-vessel arterial or venous occlusive disease, embolism, and hemorrhages (subarachnoid or intraparenchymal). SLE patients with antiphospholipid syndrome require anticoagulation therapy. Libman-Sacks endocarditis can cause embolic disease, either associated with or occurring independently of antiphospholipid antibodies.

It is crucial to emphasize that, although radiologists almost always list CNS vasculitis as a potential cause of strokes in neuroimaging reports, *CNS vasculitis is an extraordinarily rare cause of SLE cerebrovascular disease.*²¹ Most cases of cerebrovascular disease are caused by a bland vasculopathy and may be mediated by risk factors for atherosclerosis also seen in the non-SLE population. Therefore the isolated presence of strokes is not an indication for immunosuppressive therapy. However, the implication of atherosclerotic disease is different in an SLE patient than in a non-SLE patient, given that atherosclerosis in SLE patients is associated with different inflammatory biomarkers, is increased 5-fold to 10-fold compared with the general population,²² and doubtlessly represents a convergence of different facets of disease activity and damage.

Seizures. Seizures have been described in 6% to 51% of different cohorts, but in unselected cohorts the reported frequency is between 5% and 20% of patients.²² Seizures that occur within the first years of SLE diagnosis can be attributed to SLE in more than 80% of cases, may be associated with high disease activity, are more frequent in blacks, can be associated with cumulative organ damage, and have not been uniformly associated with the presence of antiphospholipid antibodies.²³ Therefore treatment of background SLE activity may lead to decreased risk of recurrent seizures and antiepileptic therapy may not be required. Nevertheless, an SLE patient with new-onset seizures needs to be evaluated for non-SLE causes, including CNS infections, metabolic disorders (including uremia), and malignancies. The decision about whether ongoing antiepileptic therapy is warranted may depend on the presence of structural injury and the severity of electroencephalographic changes.

Cognitive impairment. Cognitive impairment can affect up to 80% of SLE patient within 10 years of initial diagnosis, is present at time of initial SLE diagnosis in 60% of patients, is not associated with disease activity, and does not have a progressive course.²⁴ Mild degrees of cognitive impairment (defined by the ACR NPSLE criteria as impairment in fewer than three of eight cognitive domains) is also seen in control subjects with other diseases and may not reflect unique SLE mechanisms.¹⁹ Treatment is specifically directed at detecting other causes of cognitive impairment, including small-vessel ischemia, metabolic abnormalities (including uremia), and endocrine disorders (including hypothyroidism).

Psychosis and depression. Psychosis may occur in up to 5% of SLE patients.²⁵ The clinician should consider vascular, infectious, traumatic, neoplastic, and structural causes. However, once alternative causes have been excluded, a diagnostic challenge is whether psychosis in a patient with high SLE activity stems from SLE or is confounded by and occurring due to the high-dose corticosteroids used to treat active SLE. If SLE activity has been adequately controlled, making this distinction may require empirically lowering the dose of corticosteroids and seeing whether there is clearing of the sensorium.

Other CNS manifestations. Aseptic meningitis and movement disorders are described in fewer than 1% of cases¹⁶ but are also infrequent in nondiseased control subjects and may therefore represent the CNS spectrum of NPSLE. Nevertheless, infections and other non-SLE causes need to be pursued. Aseptic meningitis due to use of nonsteroidal antiinflammatory drugs is rare but should be considered.

Diagnostic evaluation

As has been repeatedly emphasized, the first task is to use the VITAMINS mnemonic (see Box 39.2) to help distinguish whether a CNS syndrome is attributable to SLE or to a non-SLE cause. The possibility of an infection must always be relentlessly pursued. The initial evaluation also seeks to identify clinical or laboratory stigmata of active SLE disease, with the

recognition that activity in the CNS compartment may not be mirrored by findings on serologic studies. Laboratory evaluation is also important to uncover metabolic derangements associated with specific CNS syndromes; for example, uremia leading to seizures. In most cases, more severe CNS manifestations will require neuroimaging approaches. A computed axial tomographic scan can rapidly exclude most hemorrhagic events. However, different sequences on magnetic resonance neuroimaging are required for identification of a particular CNS process (e.g., strokes as can be identified on diffusion-weighted imaging), to more precisely localize clinical deficits, and to also help elucidate surrogate features indicative of CNS pathologic processes (e.g., T2 hyperintensities that may reflect edema or microvascular disease).²² Lumbar puncture studies constitute an important part of the diagnostic process and are used to help exclude opportunistic infections as a cause of a specific CNS syndrome. Electroencephalography can be used to capture seizures or abnormal interictal phenomenon. Other neuroimaging approaches, such as diffusion tensor imaging and positron emission tomography, currently are used primarily for research purposes.

Diagnostic and mechanistic implications of the association of antibodies with CNS syndromes

Antiphospholipid antibodies. Currently, the only association between antibodies and CNS disorders that has diagnostic and therapeutic implications is the detection of antiphospholipid antibodies in patients experiencing CNS thrombotic episodes. The occurrence of such thrombotic strokes in SLE patients who satisfy the laboratory criteria for antiphospholipid syndrome justifies treatment with anticoagulants.²⁶ Cross-sectional studies have reported conflicting evidence about whether antiphospholipid antibodies are associated with nonthrombotic CNS manifestations such as seizures.²⁷ Anticoagulation is not warranted in these situations.

Anti-ribosomal P protein and anti-N-methyl-D-aspartate antibodies. *In vitro* and animal model studies suggested a potential pathogenic role of antibodies directed against the NR2 portion of N-methyl-D-aspartate (NMDA) glutamate receptors in the development of cognitive impairment.²⁸ However, an association between anti-NR2 glutamate receptor antibodies and cognitive impairment has not been consistently demonstrated in SLE patients. Similarly, the results of studies reporting an association between anti-ribosomal P protein antibodies and psychosis have not been consistently replicated. Therefore anti-ribosomal P antibodies and anti-NMDA antibodies do not currently have a diagnostic role in clinical practice.

Nevertheless, the association between anti-NR2 glutamate receptor antibodies and cognitive impairment is especially compelling given that NMDA receptors are enriched in the forebrain and hippocampus and have a role in learning and memory. Therefore the following discussion considers why there may still be an etiopathogenic role for such antibodies, despite the lack of an association with phenotypes in observational studies.

Mechanisms of CNS NPSLE

In many rheumatic syndromes, demonstrating a statistically significant association between the presence of a given antibody and an observed phenotype is often considered as a prerequisite step in showing that such an antibody is pathogenic. However, when it comes to highly complex CNS neuroinflammatory syndromes, it may be conceptually unrealistic to expect that any antibody—no matter how potentially pathogenic—might be associated with a phenotype solely on a statistical basis.

There are many stochastic steps that may need to occur for even a pathogenic antibody to be associated with a particular phenotype. For example, a peripherally generated antibody in the serum may need access to the CNS compartment and require other triggers to breach the blood-brain barrier. Interestingly, disruption of the blood-brain barrier was required before anti-NR2 antibodies were associated with cognitive impairment in the murine animal model.²⁸ Once an antibody is within the CNS compartment, its pathogenicity may be further amplified or mitigated by cytokines, which may alter the inflammatory microenvironment. Therefore epidemiologic studies may need to be integrated with *in vitro* and animal model studies to consider pathogenicity using a conceptual as well as a statistical framework.

In addition to antibodies, the two other mechanisms of NPSLE include a vasculopathy that is bland and affects the microangiopathic circulation, as well as cytokines and other immunologic signatures.²² These mechanisms may interact either to precipitate or to sustain a given phenotype; for example, triggers of a microangiopathy may afford access of an antibody to the CNS compartment.

Therapeutic strategies in the treatment of neuropsychiatric systemic lupus erythematosus

Treatment of NPSLE depends on the specific neurologic manifestation but generally requires distinguishing between SLE or non-SLE causes, noting the presence of background SLE activity, and considering whether SLE causes are related to active lupus disease or noninflammatory mechanisms. In general, mild cognitive impairment, depression, and headache can be managed symptomatically as in the non-SLE population.²⁹ As in Sjögren syndrome and RA, the only axonal neuropathies that require immunosuppressive therapy are vasculitic neuropathies. In patients with seizures, eradication of SLE activity may not require ongoing immunosuppressive or antiepileptic therapy. As noted previously, strokes are almost never associated with vasculitis, do not require immunosuppressive therapy if not associated with active SLE disease, and warrant anticoagulation when associated with antiphospholipid syndrome.²⁶ For the uncommon SLE patient who may require immunosuppressive therapy strictly because of CNS disease, regimens targeting the induction and maintenance of remission that are used in other end-organ disease (e.g., cyclophosphamide for SLE renal disease) may be considered.

The most salient point, however, is that in the majority of SLE patients, the isolated manifestation of CNS disease does not require such immunosuppressive therapy.

CENTRAL NERVOUS SYSTEM MANIFESTATIONS OF SJÖGREN SYNDROME

Among all of the CNS and PNS manifestations associated with rheumatic disorders, the CNS complications of Sjögren syndrome may have led to the greatest quandaries, disagreement, and subsequent consternation, even regarding such basic issues as disease prevalence³⁰—to say nothing of conflicting accounts as to whether certain neurologic disorders even exist in Sjögren syndrome. This has engendered great uncertainty about core issues including diagnostic workup and therapeutic strategies.

Uniform criteria have not been developed for the CNS manifestations of Sjögren syndrome, and unlike the heterogeneous PNS counterparts, the CNS manifestations remain poorly parsed and explicated. Therefore it is first relevant to consider how to define CNS Sjögren syndrome. As in SLE patients, the spectrum of Sjögren CNS manifestations is more clearly demarcated by considering disease specificity (i.e., whether specific CNS manifestations are more common in patients with Sjögren syndrome than in other cohorts) and also by considering mechanistic specificity (i.e., whether CNS manifestations may reflect etiopathogenic mechanisms that are unique to Sjögren syndrome patients).

Diffuse central nervous system syndromes *Frequently occurring diffuse CNS syndromes that are not specific to Sjögren syndrome compared with the general population*

Just as it was found that some CNS neurologic syndromes included in the ACR NPSLE nomenclature are seen with similar frequency in nondiseased cohorts,³¹ many diffuse CNS syndromes that occur in Sjögren syndrome patients likely occur with similar frequency in the general population. Such CNS syndromes include mild cognitive impairment, depression, and anxiety. The therapeutic implications are that such diffuse CNS syndromes can be managed symptomatically, with the caveat that Sjögren syndrome patients may be more vulnerable to anticholinergic adverse effects of medications.

Infrequently occurring diffuse CNS syndromes that may be more specific to Sjögren syndrome

Although aseptic meningitis and meningoencephalitis are infrequent manifestations of Sjögren syndrome (less than 1% prevalence), these CNS syndromes have been richly described across different Sjögren cohorts,^{30,32,33} are seen with even greater rarity in the general population, and can therefore be conceptualized as part of the spectrum of CNS Sjögren syndrome. The diagnostic workup should seek to rule out non-Sjögren causes as detailed in the section on NPSLE.

Cognitive impairment in Sjögren syndrome: uncertain aspects of disease specificity

More than one third of Sjögren syndrome patients describe cognitive symptoms using the metaphor of “brain fog.”³² This vivid metaphor suggests involvement of *subcortical* brain regions, with Sjögren syndrome patients frequently experiencing poor concentration, difficulty multitasking, and

shortened attention spans. However, specific *cortical* domains that are conventionally assessed in the Mini-Mental State Examination—which includes the “a” domains such as acalculia, aphasia, agraphia, and alexia—are characteristically spared.

Neuropsychologic testing frequently uncovers impairment of subcortical domains and should therefore be considered for Sjögren syndrome patients who have distressing cognitive symptoms. All Sjögren syndrome patients with cognitive impairment should be screened for depression, fatigue, endocrine abnormalities (particularly hypothyroidism), and fibromyalgia, especially given that Sjögren syndrome patients reporting cognitive symptoms have an increased frequency of fibromyalgia and depression.³² Further studies are warranted to understand whether pain and fatigue are modifiable risk factors for cognitive impairment. Unlike in SLE, there are no known or novel antibody specificities associated with cognitive impairment. Immunomodulatory approaches are not warranted.

Focal CNS syndromes that are not associated with disease-specific mechanisms and may not be part of the spectrum of CNS Sjögren syndrome

Strokes and seizures have been described in select cohorts enriched with patients with neurologic disease but are infrequent in unselected Sjögren syndrome patients. Unlike SLE patients, Sjögren syndrome patients have not been consistently demonstrated to have an underlying CNS vasculopathy³³ and generally do not have a higher frequency of antiphospholipid antibodies than the general population. Therefore it is not surprising that such focal syndromes are uncommon in Sjögren syndrome patients, and future studies are warranted to see whether the frequency of strokes and seizures is even increased in these patients compared with healthy controls.

CNS vasculitis is frequently mentioned as an unsettling possibility in the radiographic differential diagnosis for a Sjögren syndrome patient with non-specific white-matter lesions on brain MRI. As in SLE, it should be emphasized that CNS vasculitis is among the rarest of CNS manifestations and almost never occurs in Sjögren syndrome, regardless of whether Sjögren syndrome patients present with diffuse or focal syndromes. Therefore, for most CNS manifestations, immunosuppressive therapy is seldom warranted. The exception is the demyelinating syndromes, which are covered at the end of this chapter.

CENTRAL NERVOUS SYSTEM MANIFESTATIONS OF RHEUMATOID ARTHRITIS

Spinal misalignment in RA patients can cause myelopathies or frank cord compression due to C1-C2 atlantoaxial subluxation.¹¹ Although weakness of the arms and legs may be the latest findings, clinicians should be vigilant for earlier symptoms and neurologic findings in RA patients, including new onset of neck pain, occipital neuralgia, isolated lower extremity weakness, hyperreflexia, and urinary frequency due to a spastic bladder. Evidence of C1-C2 subluxation is sought by plain radiography (using anteroposterior, flexion, lateral, open mouth, and extension views) with more than a 9-mm separation between C2 odontoid and axis (anterior subluxation) associated with increased risk of cord compression. MRI is ideal for visualizing the spinal or brain stem compression but may underestimate the extent of C1-C2 subluxation as seen on plain radiographs.

Subaxial subluxation is a rare manifestation occurring due to rostral migration of the odontoid peg through the foramen magnum. Symptoms and examination findings can include new onset of vertigo, difficulty swallowing, change in voice, and diplopia. *Brain stem compression* is life-threatening and needs to be evaluated by imaging studies, including plain radiography and MRI.

Patients with subluxation often have increased disease activity or duration, seropositive disease, high levels of inflammatory markers, and bony erosions in peripheral joints. An RA patient with evidence of subluxation should be referred to an experienced orthopedic surgeon or neurosurgeon. Other CNS manifestations include pachymeningitis and nodules occurring in different anatomic regions (e.g., in the choroid plexus or extradurally in the brain or spinal cord¹¹) and have been described in case reports or small case series to respond to biologic agents.

CENTRAL NERVOUS SYSTEM MANIFESTATIONS OF SCLERODERMA

CNS manifestations directly attributable to scleroderma are uncommon, and most syndromes should therefore prompt a search for alternative diagnostic

explanations. Posterior reversible encephalopathy syndrome has been described in scleroderma renal crisis and can cause encephalopathy, seizures, and cortical blindness. Parry-Romberg syndrome has been described as a rare CNS complication in patients with coup de sabre lesions and associated osteocartilaginous atrophy.³⁴ Hemispheric involvement ipsilateral to these lesions can cause focal syndromes, encephalopathies, and seizures, which can secondarily generalize. An inflammatory cause is suggested by the improvement of encephalopathy and seizures in response to immunosuppressive therapies.

DEMYELINATING SYNDROMES IN RHEUMATIC DISEASES: DISTINCTION FROM MULTIPLE SCLEROSIS

Distinguishing between demyelinating syndromes in rheumatic diseases such as SLE and primary demyelinating syndromes (e.g., multiple sclerosis [MS] and idiopathic transverse myelitis) is frequently regarded as challenging. However, most rheumatic patients affected by demyelinating syndromes have clinical phenotypes, antibody findings, and neuroimaging findings that are highly unusual and atypical for MS.

For example, literature stemming from the 1970s referred to SLE patients with demyelinating syndromes as having “lupoid sclerosis”³⁵ based on the premise that demyelinating disease in SLE and MS have overlapping clinical and mechanistic features. Such vernacular is embedded in the ACR NPSLE case definitions, which define demyelinating syndromes using older MS definitions and consider demyelinating syndromes such as SLE myelitis to be single diagnostic entities. However, it was recently identified that SLE myelitis encompasses two distinct syndromes—gray-matter myelitis and white-matter myelitis—with both syndromes easily distinguished from MS on initial evaluation.³⁶

SLE patients with gray-matter myelitis have clinical findings suggestive of gray-matter necrosis (e.g., flaccidity and paraplegia), with hyperacute evolution to irreversible paraplegia highly suggestive of spinal cord infarction. Furthermore, it was noted that all patients with gray-matter myelitis invariably had urinary retention occurring hours to days before irreversible

paraplegia and were fully ambulatory without any motor deficits at the time of urinary retention.

Therefore all SLE patients with unexplained urinary retention (especially those with high SLE activity) should potentially be regarded as being at high risk of cataclysmic cord infarction and should strongly be considered for pulse corticosteroid therapy.

In contrast, SLE patients with white-matter myelitis can have features overlapping those seen in neuromyelitis optica (NMO; also known as *Devic disease*). Such patients with white-matter myelitis and features of NMO have attacks of optic neuritis and myelitis that are usually more severe than those in MS, have spinal cord lesions that span more than three vertebral segments, and may have antibodies directed against aquaporin-4 (i.e., the NMO-immunoglobulin G antibody³⁶).

Similarly, Sjögren syndrome patients are more likely to have demyelinating syndromes that are consistent with NMO than with MS. Furthermore, both SLE and Sjögren syndrome patients with demyelinating syndromes usually have brain lesions that are not characteristic of MS.

In summary, by focusing on clinical phenotypes of demyelinating syndromes in rheumatic diseases, diagnostic distinction from MS can be achieved. The relationship between NMO and rheumatic syndromes requires further study.

CONCLUSION

This chapter has emphasized a paradigm whereby meticulous classification of neurologic phenotypes can be a rewarding step in the evaluation of rheumatology patients with neurologic disease. When such an approach is used, diagnostic strategies are more clearly articulated, attribution of neurologic disorders to rheumatic disease versus comorbidities is more clearly understood, and the decision about whether to institute symptomatic or immunosuppressive strategies is made more rationally. At the heart of elucidating such phenotypes is the power and beauty of integrating symptoms with a neurologic examination. With such an approach, the interface between the nervous system and rheumatic syndromes can be illuminated by future biomarker studies, which can lead to exciting insights that can improve diagnosis and suggest novel therapeutic strategies.

EVALUATION: IMAGING TECHNIQUES

40

Conventional radiography and computed tomography

■ STACY E. SMITH

- Conventional radiography has a major role in, and remains the mainstay of, initial evaluation and follow-up of rheumatologic disease.
- Although the majority of joints may be adequately assessed using orthogonal radiographic plain film views, specialized views may be required for some joints (e.g., Norgaard views for the hand and a modified anteroposterior Ferguson view for the sacrum).
- Multidetector computed tomography (MDCT) provides excellent contrast and delineation of cortical and trabecular bone and is established as a superb diagnostic tool for visualization of subtle cortical or intraosseous lesions not visible on standard radiography due to projectional superimposition. In particular, CT evaluation of osteoarthritis and rheumatoid arthritis before and after treatment has proven more reliable than evaluation via digital radiography.
- Dual-energy CT has proven useful in evaluating gout and monitoring its treatment.
- CT-guided facet, joint, or bursal injections or aspirations are often used in the diagnosis and treatment of rheumatologic disease.
- CT angiography is useful for diagnosis and evaluation of the large-vessel vasculitides, particularly giant cell arteritis and Takayasu arteritis, with some studies reporting utility in monitoring treatment response.

CONVENTIONAL RADIOGRAPHY

Conventional radiography is the most common and least expensive modality for imaging and evaluating patients with rheumatologic disorders. In particular, it is the mainstay of initial evaluation of the hands, wrists, feet, and sacroiliac (SI) joints.

Uses

The radiographic assessment of bones and joints includes evaluation of all the following: presence or absence of bone loss or bone production; joint space narrowing (an indirect sign of articular cartilage thinning) or widening; presence or absence of calcification/chondrocalcinosis, ankylosis, subluxation, or dislocation; changes in bone mineral density; and gross soft tissue abnormalities (Fig. 40.1). Interpretation of the radiographs requires a sound knowledge of radiographic anatomy; the patient's clinical presentation, symptoms, and laboratory information; and disease pathologic processes to provide the most correct diagnosis and/or differential diagnosis. The comparison of bilateral joints can further enhance the detection of subtle abnormalities, allowing for assessment of bilateral involvement and symmetry (Fig. 40.2). Serial radiographs can be used for staging, monitoring, and assessing treatment efficacy. Validated methods for scoring

radiologic damage in joints have been developed by several authors and used extensively in clinical trials, particularly those examining osteoarthritis and rheumatoid arthritis (see Chapters 45 and 178).^{1,2}

Conventional radiography does have limitations, however, including a wide variation in image quality, an inability to evaluate the very early stages of inflammatory disease in bone and soft tissue (e.g., synovitis), and the projectional superimposition of structures due to the two-dimensional (2D) representation of three-dimensional (3D) structures in a single plane. Wide variations in image quality (differences in projection and penetration) make it vital to ensure proper exposure and accurate positioning of serial shots to obtain accurate results and to provide a true comparison with prior studies.

The inability to evaluate the very early stages of inflammatory disease (early erosions, articular cartilage abnormalities, and synovitis) is due to the insensitivity of radiographs to both the trabecular bone loss and the intramedullary component of early bone erosions as well as the lack of soft tissue detail. Magnetic resonance imaging (MRI) and ultrasonography have both been reported to be more sensitive than conventional radiography in detecting these early changes, particularly articular cartilage abnormalities and early erosions.³ Radiography has been found to be more suitable for detecting cortical bone loss, which is a later phenomenon. As a result, radiography has proven useful as the mainstay for confirming established disease and for following the known disease process, with MRI being more sensitive in predicting which patients will not experience progression of disease in clinical trials and in detecting which will be predisposed to disease (early soft tissue changes).⁴ The use of radiography as the first line of defense in early diagnosis of bisphosphonate-related femoral fractures has been crucial recently in avoiding potential complete femoral shaft fracture and its ensuing complications. Imaging characteristics in such cases include a “beaklike” lateral cortical subtrochanteric femoral fracture deformity (Fig. 40.3). This entity is seen more commonly in female patients who have been treated with bisphosphonates (e.g., alendronate) for longer than 5 years.

Projection views

The projectional nature of radiography can lead to superimposition of overlapping structures. In rheumatoid arthritis this can obscure *en-face* erosions. For this reason articular disorders and disorders affecting the axial skeleton should be evaluated in at least two orthogonal planes (sometimes three, depending on the specific joint or anatomy) to increase the diagnostic sensitivity and allow full evaluation of the extent of the disease process. In the majority of patients imaging is therefore performed using two orthogonal views: a routine anteroposterior (AP) or posteroanterior (PA) view and an accompanying 90-degree lateral view (Fig. 40.4). Specialized views and techniques have also been developed that have been invaluable in allowing assessment of specific disease processes in certain joints. Such specialized views include the Norgaard view for the hand and wrist (see Fig. 40.4) and the modified AP Ferguson view for the SI joints (Fig. 40.5). Suggested routine radiographic techniques as well as some of the more specialized techniques and projections are listed in Box 40.1.⁵

Fig. 40.1 Radiographic assessment for disease-related criteria. (a) Anteroposterior (AP) view of the metacarpophalangeal (MCP) joints in a disease- and trauma-free patient showing normal joint spaces, soft tissues, and cortical/intramedullary integrity. (b) AP view of the MCP joints with narrowing and subluxation of the joints, periarticular osteopenia, and subtle marginal cortical erosions in a patient with rheumatoid arthritis. Lupus can present as similar subluxation but without cortical erosion. (c) AP view of an MCP joint with soft tissue swelling, cortical erosions, and destruction of both sides of the joint in a patient with chronic joint infection. (d) AP view of the MCP joints with osteopenia and multiple soft tissue calcifications about the joints in a pediatric patient with rheumatoid factor–positive mixed connective tissue disease.

Hand and wrist

Although the PA view of the hand and wrist is the best conventional view for assessment of malalignment, joint space narrowing, soft tissue abnormalities, and mineralization, it is of limited use for assessment of erosive changes. The Norgaard view (sometimes referred to as the *ball catcher's view*; see Fig. 40.4) is an AP oblique view of the hand and wrist that profiles both the radial aspect of the base of the proximal phalanges in the hand and the triquetral pisiform joint, two areas where the earliest erosive changes of any inflammatory arthropathy occur. Because the fingers are not rigidly positioned by the radiographer in this view, the reducible subluxations of inflammatory arthropathies and systemic lupus arthropathy also may be easily seen.

Sacroiliac joints

The modified AP Ferguson view (see Fig. 40.5) allows the best visualization of the anteroinferior-most portion of the SI joints. This is important histologically because the lower half to two thirds of the SI joint is a true synovial joint and is the area most frequently affected by rheumatologic disorders. To obtain the Ferguson view, the patient is placed supine with knees and hips flexed. The x-ray tube is centered at L5-S1 and angled 25 to 30 degrees toward the head to best profile the SI joint. It is essentially a centrally

Fig. 40.2 Rheumatoid arthritis. Bilateral posteroanterior hand radiographs demonstrate multiple erosions involving predominantly the proximal interphalangeal and metacarpophalangeal joints. Assessment of bilateral involvement and symmetry is helpful in narrowing the differential diagnosis.

Fig. 40.3 Anteroposterior view of the right femur depicting "beaklike" focal lateral cortical thickening of the subtrochanteric femoral diaphysis characteristic of a bisphosphonate-related fracture.

coned-down modification of a pelvic outlet view directed perpendicular to the sacral inclination to allow *en-face* visualization of the entire sacrum.

Knees

Another modification of radiographic technique involves the imaging assessment of the knees. AP or PA semiflexed views of the knees are best performed with the patient in the standing (weight-bearing position) rather than the supine position so as to best assess for cartilage loss. Medial and lateral femoral tibial joints may appear symmetric and normal in a supinely

Fig. 40.4 Standard orthogonal views and specialized radiographic views. Anteroposterior (a) and lateral (b) views of a normal hand depict three-dimensional anatomic structures in two-dimensional projection correcting for possible overlap of structures if imaged in only one plane. Bilateral Norgaard view (ball catcher's view) (c) of normal hands and wrists allows better visualization of the pisotriquetral joint, first and second carpometacarpal joints, and lateral cortical margins of the second to fifth proximal phalangeal bases. Early erosive changes are best seen at these locations.

positioned patient, whereas the standing images can reveal true early joint space loss. Joint space width of less than 4 mm has been reported to be consistent with cartilage loss.

Choice of joints

For patients with suspected polyarticular disorders, some authors suggest that survey radiographs of the hand and forefoot typically can provide the highest yield with the least amount of radiation exposure. Survey radiographs may be obtained for initial evaluation and at various intervals during subsequent examinations. The anatomic regions included in the survey depend on the specific disorder suspected clinically, its distribution, and laboratory findings and must reveal enough information to delineate the type and extent of the disorder without representing an overuse of the patient's, technician's, and physician's time or excessive radiation exposure and expense. Sartorius and Resnick suggest a minimum detailed high-yield radiographic survey for such investigations (see Box 40.1).⁶ Modifications to the survey are expected depending on the clinical and laboratory situation, and follow-up radiographs are not as extensive as the initial survey because they are tailored to the regions of specific interest.

Techniques and physics

X-rays are produced when highly energetic electrons interact with matter and convert their kinetic energy into electromagnetic radiation. The combination of an x-ray tube, x-ray tube housing (for shielding), x-ray field, and generator (the energy source that supplies the voltage to accelerate the

electrons and also controls voltage, current, and exposure time contributing to x-ray output) creates an x-ray beam of well-defined intensity for penetrability and spatial distribution (Fig. 40.6). Projection imaging (acquisition of a 2D image of the patient's 3D anatomy, i.e., radiography) compresses anatomic structures, concentrating the entire thickness of the patient's body into one single image known as the *radiograph*. This type of radiographic system uses the film-screen combination, consisting of a cassette, one or two intensifying screens (which decrease the radiation dose to the patient but can cause loss of spatial resolution), and a sheet of film (single or double photosensitive emulsion). Double-screen, double-emulsion film-screen systems are most commonly used for routine clinical radiography, whereas high-efficiency single-screen, single-emulsion film-screen combinations or single-emulsion film without screens is preferred for high-quality, high-resolution radiography, particularly in assessing therapeutic response to treatment of disease.

Magnification radiography

The quality of the radiographic image is important for accurate and detailed assessment of subtle skeletal abnormalities. High-resolution magnification radiography and fine-detail radiographs were developed to maximize diagnostic information. These are particularly useful in assessment of the hands, fingers, and feet. Magnification radiography is a highly specialized, not commonly available radiographic technique that results in higher resolution (sharpness), better contrast, and lower quantum noise than conventional radiography and is used primarily for research purposes.⁷ Image magnification up to 10 times that seen in conventional radiographs can be obtained. It is more sensitive than conventional radiography in detecting erosions,

Fig. 40.5 Ferguson view of the sacrum and sacroiliac (SI) joint evaluation. Better visualization of the anteroinferior SI joints is noted in the specialized Ferguson view (a) than in the standard AP view (b) of the sacrum in a normal patient. Ferguson view in a patient with ankylosing spondylitis (c) shows apparent complete fusion of bilateral SI joints. Coronal multiplanar reconstructed computed tomographic image of the SI joints in the same patient (d) better depicts near-complete fusion of the SI joints.

patterns of bone resorption, early bone proliferation, chondrocalcinosis (i.e., crystal deposition disease [calcium pyrophosphate dihydrate deposition disease, or CPPD]), and the presence of soft tissue swelling and is useful when conventional radiography yields negative or equivocal findings. Fine-detail radiography is more sensitive in detecting the subtle early subperiosteal resorption, cortical striation, or tunneling seen in hyperparathyroidism.⁶ It may also be helpful in monitoring the course of this disease and its response to therapy.

Two forms of magnification radiography have been used:

1. *Optical magnification of fine-grain films.* The exposure obtained with conventional radiographic equipment and fine-grain industrial films is viewed with optical enlargement. Although increased radiation dose is noted with this technique, it has been used in the investigation of both metabolic and arthritic disorders by Genant⁸ and others, with good reproducibility.
2. *Direct radiographic magnification for skeletal radiography.* A small focal spot (100 to 150 μm) is used in this technique, which has received less attention than optical magnification, with only a few reports of its use in the literature.^{9,10} It is associated with fourfold increase in skin dose (exposure per surface area), but the use of a rare earth screen-film system and single-emulsion, single-screen systems as well as a decreased field of view can significantly counteract and reduce the total-body irradiation of this technique.

Digital radiography

Digital radiography has grown in popularity to become the mainstay of radiography given the current “filmless” digital age in radiology departments. This technique is more expensive because it requires high luminance and high-resolution monitors to view the digital image, generates large data sets that require large amounts of space on digital storage media, and depends on a high network bandwidth for picture archiving and communication systems (PACS).

The four main systems currently available for acquisition of digital radiographs are the following:

1. Computed radiography using photostimulable phosphor detector systems in which images are stored and viewed on PACS yet can be printed directly via a laser printer
2. Charge-coupled devices used in fluoroscopy
3. Direct detection flat-panel systems
4. Indirect detection flat-panel systems

Direct detection systems use a photoconductor material (usually selenium) applied on top of a thin film transistor array, whereas indirect systems use an x-ray–intensifying screen that converts x-rays to light, which is then detected by the flat-panel detector. The principal advantage of direct detection over indirect detection flat-panel systems is a decrease in blurring; direct detection systems have a higher spatial resolution than

BOX 40.1 STANDARD AND SPECIALIZED RADIOGRAPHIC PROJECTIONS

Adequate radiographic evaluation requires at least two orthogonal projections.

Standard radiographs**Finger:**

- PA projection
- Lateral projection

Hand:

- PA projection
 - Oblique projection (45-degree semipronated or semisupinated)
 - Lateral projection
- Magnification views are more sensitive for evaluating erosive disease, if available.

Wrist:

- PA projection (arm abducted 90 degrees from trunk and forearm flexed at 90 degrees to the arm)
- Oblique projections
- AP oblique view (Norgaard or ball catcher's view)
- Lateral projection

Foot:

- AP, oblique, and lateral views

Shoulder:

- AP views (in true external and internal rotation)

Knee:

- AP (standing semiflexed position to allow accurate evaluation of cartilage loss)
- Flexed lateral (nonstanding to allow patellofemoral evaluation) ± sunrise or Merchant patellar view and ± tunnel views

Hip:

- AP (best for femoral neck evaluation)
- Frog-leg lateral projection (best for femoral head evaluation and investigation of avascular necrosis)

Sacroiliac joints:

- Modified AP Ferguson view

Spine:

- AP and lateral views

Survey radiographs***Hands:**

- PA projection
- Semipronated oblique view

Wrists:

- PA projection
- Lateral projection
- Obliques (semipronated and semisupinated)

Shoulders:

- AP 40-degree posterior oblique view

Feet:

- Medial oblique view

Ankles:

- Lateral view including heel

Knees:

- AP projection
- Lateral projection

Pelvis:

- AP projection

Cervical spine:

- Lateral with neck flexion

*The survey requires modification depending on specific diagnosis and clinical questions (e.g., suspected ankylosing spondylitis) or emphasis on axial skeleton including sacroiliac joints (e.g., suspected calcium pyrophosphate dihydrate deposition disease), symphysis pubis, PA wrist, and AP knees.

AP, anteroposterior; PA, posteroanterior.

Fig. 40.6 The x-ray tube consists of a cathode tube filament producing electrons, a tungsten target in a copper anode, and a vacuum tube.

Computerized x-ray image analysis methods (computer-aided analysis)

Computer-aided analysis or computer-aided detection of radiographic data was developed to fill the need for quantitative surrogate outcome measures in clinical research. Large numbers of radiographs could be digitally imaged and stored by the computer software system for evaluation and training. These methods were initially used in mammographic and chest imaging. The computer algorithm was developed to be able to detect nodules and lesions and classify them as benign or malignant. Their utility in arthritis research is increasing.¹² Most of the work in developing computerized digital radiograph-based techniques in rheumatology has focused on the evaluation of osteoarthritis of the knee; more recent studies have involved the hip and hand, with the latter focusing on analyses of the metacarpophalangeal and proximal interphalangeal joints in rheumatoid arthritis.^{13,14}

The general goal of such systems is to quantify arthritis progression by measuring the radiographic minimum joint space width by way of a computer software algorithm that can delineate the opposing margins of a joint on a digital radiographic image (Fig. 40.8). Although computerized techniques are objective and fast, they are prone to occasional error, and as a result, a quality assurance step is necessary that allows for correction. Overall, however, these systems are reproducible, providing a more objective measurement with improved interreader and intrareader reproducibility, and are more efficient and cost effective than manual scoring systems.¹²

Interventional techniques

There is an increasing use of interventional conventional radiography in rheumatology, of which fluoroscopically guided injection of joints for diagnosis or therapeutic intervention is the most important. Although advanced imaging (MRI or computed tomography [CT]) is more commonly used for assessment of synovial thickening, ligament degeneration or tear, or osteochondral bodies, fluoroscopically guided arthrography can be used in those patients who are claustrophobic or who are not candidates for MRI. Indeed, this latter technique can be useful, for example, in demonstrating some reliable indicators of synovial inflammation, such as corrugated irregularity of injected intraarticular contrast material within the wrist or glenohumeral joint, enlargement of the joint, and opacification of lymphatic vessels.¹⁵ Degeneration of the triangular fibrocartilage complex with eventual tear can be documented under fluoroscopy after injection of the radiocarpal joint as visualized leakage of contrast agent into the distal radial ulnar joint (Fig. 40.9). Osteochondral bodies can be seen as filling defects within the joints on arthrography of the shoulder, which help in diagnosis of osteochondromatosis.

Therapeutic injections include corticosteroid or analgesic injections into the joints, most commonly the shoulder, SI joints, or hips. Other substances that have been injected under fluoroscopy include cartilage-stimulating or

either computed radiography or indirect systems, require a lower radiation dose than conventional plain film radiography, and have improved tolerance for overexposure or underexposure (too bright or too dark images) because of a wider dynamic range (Fig. 40.7). The anatomic detail, contrast, and spatial resolution of these digital techniques have been found to be sufficient for the evaluation of arthritis.¹¹

Fig. 40.7 Comparison of 100-speed conventional film-screen combination (a and b) and direct detection flat-panel system using selenium detectors (c). The voltage is 50 kV with exposure cut from 4.0 mAs in (a) to 0.56 mAs in (b and c). The conventional film-screen combination provides no diagnostic information (bone and articular structures) with a 50-kV 0.56-mAs exposure; however, the direct detection flat-panel system (c) provides images of diagnostic quality because of its greater dynamic range.

cartilage-replacement substances in patients with little or no cartilage remaining in the knees or hips. Injection of the joint of interest under fluoroscopic guidance may be used before MRI or CT for assessment of cartilage, joint space, ligament, and soft tissue integrity in arthritic patients; for evaluation for other causes of joint pain; and for presurgical assessment (Fig. 40.10)

Fig. 40.8 Computerized x-ray image analysis for joint space narrowing. (a) Computer-delineated femoral condyle shown as the white line overlaid on the knee radiograph. (b) Computer-determined joints along the bright band corresponding to the base of the tibial plateau. (c) Computerized determination of minimum joint space width. The points on the tibial plateau have been connected. The shortest distance between the femoral condyle and the tibial plateau is automatically detected.

COMPUTED TOMOGRAPHY

Multidetector computed tomography

Multidetector computed tomography (MDCT), also referred to as *multislice*, *multidetector-row*, or *multisection CT*, is the latest, most widely used version of CT and is now a true 3D imaging modality. Gains over the transaxial cross-sectional technique include reduced scan time, section collimation, and increased scan length with high spatial resolution. Multislice CT allows extended anatomic coverage with thinner slices (0.5-mm slice width). This makes it possible to acquire isovolumetric data (arbitrary imaging planes). Thus techniques such as multiplanar reconstruction and 3D rendering (volume rendering, shaded-surface display, and maximum-intensity projections) become an integral part of the examination (Fig. 40.11).¹⁶ The multidetector scanners obviate the need for scanning patients in multiple positions to achieve true 2D sagittal, coronal, axial, or oblique images. Multiplanar reformatted images (i.e., not only sagittal and coronal but also oblique or 3D images) can be reconstructed in any plane from the original axial data set acquired during the initial scan.

MDCT began with 4-, 10-, then 64-detector array scanners, but 128-detector array scanners are now becoming the mainstay of radiology departments. Arrays with higher numbers of detectors result in less possibility of movement artifact, which not only is of benefit in the imaging of children, ill patients, and claustrophobic individuals but is especially important in the imaging of small joints so as not to lose data or critical information during the study. Scanners with 164 and 320 detectors have now been introduced in some institutions.

One of the issues in MDCT is that image noise is increased with sectional collimation reduction (thin slices), which requires either an increase in the radiation dose or thickening of image sections to decrease the noise. This problem is diminishing with the use of scanners with higher numbers of detectors. Also, thinner slice widths are more commonly used in imaging

Fig. 40.9 Fluoroscopy. (a) Anteroposterior view of a wrist arthrogram obtained under fluoroscopy demonstrates injection of the midcarpal joint without abnormal extravasation with needle now repositioned within the radiosaphoid joint. (b) Contrast injected within the proximal radiocarpal joint shows abnormal flow into the distal radioulnar joint consistent with triangular fibrocartilage ligament tear.

Fig. 40.10 Computed tomographic (CT) arthrogram of the knee obtained for presurgical assessment. Following fluoroscopically guided intraarticular contrast injection of the knee, sagittal CT images show (a) normal cartilage thickness of the lateral femoral and tibial surfaces (black arrows) paralleling subchondral bone and (b) full-thickness cartilage loss (white arrows indicate increased density of contrast filling the defect) involving posterior medial femoral and tibial cartilage in keeping with severe osteoarthritis.

Fig. 40.11 Multidetector computed tomography (MDCT): two-dimensional (2D) and three-dimensional (3D) applications. (a) Axial MDCT image of the pelvis, just one of many thin slices in the original study database for this patient. (b and c) Coronal and sagittal multiplanar reconstruction CT images of the spine and pelvis, respectively, created from original data.

Fig. 40.11, cont'd 3D MDCT images of the spine using a volume-rendering technique in anteroposterior (d), right (e), and left (f) anterior oblique projections. *Continued*

the extremities, which do not contain radiosensitive tissue, so that radiation dose is less of an issue in these cases (Fig. 40.12).¹⁵

Applications in rheumatology

Bone

MDCT provides excellent contrast and delineation of cortical and trabecular bone and is established as a superb diagnostic tool for the visualization of subtle cortical or intraosseous lesions not visible on radiographs due to projectional superimposition (see Fig. 40.11). MDCT also allows for better detection of ossific and joint features in metabolic bone disorders and spondyloarthritis (Fig. 40.13). Although MRI and ultrasonography in experienced hands have been found to be superior to CT in detection of erosion, one study found that the scoring of erosions in the rheumatoid hand was higher with MDCT than with MRI at the metacarpal bases owing to the ability of MDCT to clearly delineate cortical bony margins and areas of sclerosis.¹⁷ MDCT provides validation of the bone damage or destruction suspected on MRI or ultrasonography and may be useful in treatment follow-up because sclerosis may be indicative of reparative changes (see Fig. 40.12).¹⁸ In a recent study comparing CT and digital radiography in the evaluation of first carpometacarpal (CMC) and scaphotrapeziotrapezoidal (STT) joint osteoarthritis, CT had a higher interreader reliability and detection rate than radiography for both first CMC and STT osteoarthritis. Because surgical treatment selection of thumb base osteoarthritis depends on the presence of pathologic changes in the first CMC and STT joints, the use of CT was thought to improve treatment selection and surgical planning.¹⁹

CT is less expensive than MRI and has a shorter scanning time, which may benefit some patients, although CT involves exposure to ionizing radiation. Because of its ability to assess both cortical and trabecular bone, CT can be used to assess for osteopenia or osteoporosis. This assessment can be made subjectively using a CT study performed for other purposes. Quantitative CT of the spine is one objective method for volumetric evaluation of bone mineral density, but it is generally reserved for research purposes. Bone mineral density evaluation and its methods are discussed in detail elsewhere (see Chapter 44).

Peripheral and axial joints

Joints that are difficult to visualize with the usual imaging techniques (apophyseal, costovertebral, sternoclavicular, and temporomandibular joints) may be better evaluated with MDCT and the use of reformatted images, maximum-intensity projections, or multiplanar reconstructions for visualization and evaluation of ligaments and bone, spinal cord compression, erosions of the odontoid process, subluxation, and presence of calcification (Fig. 40.14). The 3D analysis of standard joints such as the glenohumeral or hip joint with suspected osteoarthritis, rheumatoid arthritis, CPPD, or ischemic necrosis can be useful in assessment of subtle bone or joint changes as well as detection of any periarticular soft tissue masses or synovial cysts. The use of MDCT after intraarticular injection of a contrast agent has proved to be useful in these latter situations because even articular cartilage abnormalities can be visualized as a result of increased spatial resolution and increased delineation of bone versus cartilage (Fig. 40.15).²⁰

The CT findings of sacroiliitis are similar to those seen on conventional radiographs, including erosions, sclerosis, and eventual ankylosis if the disease progresses (see Figs. 40.5 and 40.13). Several studies indicate that CT is more sensitive than radiography in identifying sacroiliitis, leading to an earlier diagnosis of sacroiliitis and earlier implementation of treatment.²¹ CT is also useful in septic arthritis because irregular bone destruction and intraarticular or periarticular fluid is well seen, particularly after intravenous administration of a contrast agent, with the infected fluid collection demonstrating a characteristic peripheral rim enhancement pattern.²⁰

CT-guided facet, joint, or bursal injections are often used in the diagnosis and treatment of rheumatologic disease. CT fluoroscopy combines the careful delineation of anatomy with the real-time cineradiography of fluoroscopy, allowing finer visualization of placement and orientation of the procedural needle for appropriate injection or aspiration as required.

Soft tissues and vessels

CT is generally used for the evaluation of bone, but the soft tissue system can also be evaluated, although typically MRI may be a more appropriate

Fig. 40.11, cont'd (g and h) Volume-rendered 3D CT images of the pelvis and spine in coronal and sagittal projections, respectively, using bone windows. (i and j) Maximum-intensity projection images of the pelvis and hips in coronal and sagittal projections, respectively, clearly delineating the joint space and cortical integrity of the hips.

Fig. 40.12 Thin-slice 128-detector-array coronal multiplanar reconstruction computed tomographic image demonstrating healing erosions with sclerotic margins involving the second and third metacarpophalangeal joints and the first metacarpal head (arrows) in a patient with rheumatoid arthritis treated with methotrexate.

Fig. 40.13 (a) "Rugger jersey" appearance of the spine clearly depicted on sagittal multiplanar reconstruction computed tomographic (CT) image. (b) Associated axial CT image demonstrating prominent sacroiliac joint erosions, mixed sclerosis, and loss of bone density. Findings are in keeping with the patient's history of renal osteodystrophy and hyperparathyroidism.

Fig. 40.14 Rheumatoid arthritis of the odontoid. Lateral cervical spine radiograph (a) shows narrowing of the preodontoid space, osteopenia, and midcervical disk space narrowing. Multidetector computed tomographic sagittal (b), axial soft tissue (c), and bone window (d) images better demonstrate soft tissue pannus and erosions of the odontoid.

modality for imaging of these tissues. One of the more common soft tissue indications for CT in rheumatology is the evaluation of the large-vessel vasculitides using CT angiography.²² These disorders, particularly giant cell arteritis or Takayasu arteritis, can be detected, visualized, analyzed, and, according to some studies, even monitored using CT angiography, because it can evaluate both the vessel wall and the lumen and may show vessel wall alterations even when the lumen appears unaffected on standard angiography.²³ CT has a role in diagnosing both early and advanced Takayasu arteritis. In early Takayasu arteritis, CT may show arterial wall thickening with mural enhancement and low-attenuation ring on delayed images, whereas in advanced Takayasu arteritis, CT shows the typical late-stage complications, including vessel stenosis, occlusion, and aneurysm.²⁴ Aortic wall enhancement was shown to resolve after immunosuppressive therapy in 7 of 13 patients with Takayasu arteritis in one study.²⁵ CT angiography cannot visualize relatively small vessels, however, and therefore its use is limited to deep large-vessel evaluation.²⁶

Dual-energy computed tomography

Dual-energy computed tomography (DECT) has proven highly accurate for identifying uric acid calculi and differentiating it from other types of calculi (in particular, calcium) both *in vitro* and *in vivo* using specific attenuation characteristics that can identify or exclude gout.^{27,28} This technology has recently been applied to the evaluation, diagnosis, and management of gout in the musculoskeletal system.²⁹⁻³¹

DECT uses two x-ray tubes with different peak kilovoltages (80 and 140 kVp) that are used to acquire two CT image sets of a specific anatomic region simultaneously, which eliminates misregistration artifact or errors that can occur due to patient movement if the imaging is done sequentially. The chemical compositions of the scanned tissues can be differentiated by comparing the material-specific differences in attenuation using special software.³⁰ Color-coded cross-sectional images are created from postprocessing of the DECT data and can be used to create 3D surface-rendered models that are useful for visualization of tophus burden and location (Fig. 40.16). These

Fig. 40.15 Computed tomographic (CT) arthrography of the shoulder. (a) Anteroposterior fluoroscopic image of the right shoulder shows needle placement in the mid-distal third of the glenohumeral joint. (b) Contrast material subsequently injected into the glenohumeral joint is seen flowing along the curvilinear contour. (c) Axial multidetector CT scan acquired through the right shoulder joint after intraarticular injection of dilute radiographic contrast agent demonstrates the articular cartilage of the humeral head as a low-density structure (triple arrows) clearly outlined by the high-contrast material. The posterior labrum is well visualized (single arrow). (d) A more distal slice demonstrates the anterior and posterior portion of the glenoid labrum (arrows).

Fig. 40.16 Dual-energy computed tomographic (CT) images of a 72-year-old woman with history of painful left first metatarsophalangeal joint and a history of gout. Pain was thought to be due to a small spur and potential tophi seen medial to this joint on standing left foot radiograph (a). This is better depicted on CT (b) and color-coded composition (c) images obtained with postprocessing techniques showing uric acid deposits (green) within tophus distinct from the ossific calcium-containing structures (blue). Surface-rendered three-dimensional CT image (d) again clearly shows focal tophi (green) distinct from bone (purple and white). (Courtesy Dr. Mark J. Kransdorf, Mayo Clinic.)

volumetric renderings can be used in clinical trials or for routine treatment evaluation because they provide reproducible sensitive and specific volumetric quantification of tophi without significant user variability.³⁰

DECT has shown utility in the diagnosis of gout in patients with atypical manifestations, evaluation of response to treatment in patients with known gout (using serial volumetric quantification of subclinical tophi), differentiation of gout from entities that mimic gout (CPPD, rheumatoid arthritis,

progressive osteoarthritis, infection), and, in particular, evaluation of asymptomatic patients by detection of subclinical urate crystal deposits, which allows for earlier recognition and treatment before irreversible joint damage can occur. DECT can be useful regardless of the patient's serum urate levels (i.e., it can detect gout when serum urate level is normal or exclude it when it is elevated) and may help obviate the need for invasive diagnostic procedures in the acute disease setting in the future.²⁸

Functional magnetic resonance imaging

■ LAUREN M. SHAPIRO ■ STEPHEN J. MATZAT ■ GARRY E. GOLD

- Magnetic resonance imaging (MRI), with its versatility and high sensitivity, allows for a comprehensive assessment of the anatomy and pathology of the musculoskeletal system.
- Three-dimensional imaging sequences have been developed and can be used to obtain isotropic resolution allowing for image reformation in oblique planes.
- Measurement of cartilage thickness and mapping can be used to track the progress of osteoarthritis.
- T2 relaxation time measurements can help characterize the state of fibrocartilage tissues such as the menisci and ligaments by detecting changes in the cartilage matrix.
- T1rho imaging can help visualize some of the earliest biomarkers of osteoarthritis through changes in macromolecular content such as proteoglycan depletion.
- Sodium imaging is sensitive to fairly small changes in proteoglycan depletion and provides a strong method with which to study early-stage osteoarthritis.

INTRODUCTION

Magnetic resonance imaging (MRI) is an extremely versatile and highly sensitive imaging modality used to evaluate the musculoskeletal system.¹ The wide range of contrast mechanisms available for MRI and the continuing development of new software and hardware have resulted in improvements in resolution and sensitivity. Unlike radiography and computed tomography (CT), MRI does not use ionizing radiation and therefore involves no significant patient risk when used within the U.S. Food and Drug Administration guidelines. The drawbacks to MRI include the high costs of equipment and scanning, long imaging times, and potential for motion and other artifacts that may decrease image quality. Despite these limitations, the overall soft tissue contrast and flexibility have helped to establish MRI as the modality of choice for assessment of the musculoskeletal system.

OVERVIEW OF BASIC PRINCIPLES

The fundamental basis of MRI and the physical property that makes it possible is known as the *magnetic resonance (MR) phenomenon*. Atoms that possess a net nuclear spin as a result of having an odd number of protons and/or neutrons exhibit this property. Although a number of different nuclei exhibit the MR phenomenon, almost all clinical MRI is done with protium (¹H) because of its natural abundance.

MRI requires the application of a strong external magnetic field (B_0) within which protons behave like bar magnets with magnetic moments or “spins.” The magnetic moment of a single proton is not detectable, but the additive effects of many protons can be measured (Fig. 41.1). In the absence of the external magnetic field, proton magnetic moments are oriented randomly and present a net zero moment when summed together. With an applied B_0 field, however, the spins align either parallel (with the magnetic field) or antiparallel (against the magnetic field). Because a slightly greater number of protons align with rather than against the field, a small net magnetization results in the direction of B_0 .

The spins aligned with the external B_0 field precess at a known angular frequency ω given by the Larmor equation, according to which $\omega = \gamma \cdot B_0$, where γ is a constant known as the gyromagnetic ratio. An external radio-frequency (RF) field is applied at the resonant frequency that tips the spins into the transverse plane perpendicular to the main B_0 field. After the RF pulse, the spins relax back toward the z-axis aligned with the B_0 field. This relaxation results in the emission of the MRI signal and is characterized by two exponential decay constants, T1 and T2. These relaxation rates depend on the tissue properties of the sample, and it is these differences in intrinsic T1 and T2 relaxation times that are often exploited to generate MRI contrast. Free induction decay, the process of the relaxation of the spins in the transverse plane, is illustrated in Figure 41.2.

T2 relaxation

The process of free induction decay is characterized by the exponential time constant T2. The B_1 RF pulse tips the longitudinally oriented spins into the transverse plane. The angle of the tip away from the z-axis is known as the *flip angle*. When tipped into the transverse plane, the spins are coherent and aligned in one direction. Over a period of time, the spins lose phase coherence in the transverse plane and the net magnetization in the x-y plane becomes zero. This is referred to as *spin-spin relaxation*, and the exponential time constant that governs this loss of phase coherence is the T2 relaxation time. The elapsed time between the peak signal and 37% of the peak signal is the T2 decay constant (Fig. 41.3). Different tissues in the musculoskeletal system have different T2 relaxation times, which greatly impacts their appearance on MR images. T2* relaxation is another important component that contributes to the generation of image contrast. T2* is the observed time constant for the free induction decay as a result of the loss of phase coherence. T2* decay, which is present on gradient-echo MR images, is shorter than T2 decay.

T1 relaxation

Loss of transverse magnetization occurs relatively quickly, whereas recovery of the longitudinal magnetization to equilibrium takes longer. This occurs along the z-axis and is referred to as *T1 relaxation*. As this occurs, individual spins must release their energy to the local tissue by way of a process that is called *spin-lattice relaxation*. The T1 relaxation time constant is the time needed to recover 63% of the longitudinal magnetization after a 90-degree B_1 pulse tips the spins into the x-y plane. Just as different tissues have different T2 relaxation times, they have different T1 relaxation times that impact their appearance on MR images. Measured T2 and T1 relaxation times for common musculoskeletal tissues are available.²

Magnetic resonance imaging contrast

In most MRI experiments, image contrast is determined by a combination of intrinsic proton density of the tissues and the T1, T2, and T2* relaxation times. The operator of the scanner can influence the appearance of the images by changing the timing of the signal acquisition after excitation (known as *echo time [TE]*) or the time between the excitations (known as *repetition time [TR]*). Images are typically acquired using different parameters that take advantage of the different relaxation types. For example, images with a relatively short TE and TR emphasize T1 relaxation time differences and are referred to as *T1-weighted images*. Images with a long TR and long TE emphasize T2 relaxation time differences and are termed *T2-weighted images*. Images with a long TR and short TE are proton density weighted because contrast in these images is generated as a result of tissue proton-density differences.

Fig. 41.1 Diagram of the alignment of protons without the applied B_0 field (a) and with the applied B_0 field (b). Slightly more protons align parallel with the B_0 field than antiparallel, which results in a net magnetization.

Fig. 41.2 Diagram of free induction decay in magnetic resonance imaging. Immediately after excitation, the magnetization in the x-y plane (M_{xy}) is a coherent vector, which results in the maximum magnetization. As the decay proceeds, the spins lose coherence and eventually are ordered in random directions, giving a net M_{xy} of zero.

IMAGE QUALITY

An essential aspect of MRI is the ability to evaluate and compare images obtained using different techniques. A variety of strategies are available with which to assess image quality; however, the three most valuable means of comparison are contrast sensitivity, spatial resolution, and signal-to-noise ratio (SNR). Contrast sensitivity is one of the primary reasons why MRI is so useful, and it can be altered to the parameters necessary for viewing the desired anatomy or pathologic process by changing the T1 and T2 relaxation times, flow-velocity properties, and spin densities. Spatial resolution is the ability of an imaging system to distinguish between two objects as they decrease in size and move closer together. Spatial resolution depends on matrix size, field of view, and slice thickness. SNR is used to measure the amount of the desired signal in relation to the amount of background noise (or "random" signal). There are several more robust and precise methods of calculating SNR, but the most commonly used method is to divide the standard deviation of background noise from a region of interest into the mean signal from another region of interest in the same image. SNR depends on many different variables, including but not limited to field of view, coil type, slice thickness, and magnetic field strength.

Fig. 41.3 Diagram of exponential spin-spin (T2) decay. (a) After one exponential time constant T_2 , the magnetization in the x-y plane (M_{xy}) has decayed to 37%. (b) Gradient-echo methods demonstrate T_2^* decay, which is faster than T_2 decay. Spin-echo methods in magnetic resonance imaging refocus the T_2^* decay, which results in T_2 decay.

CONVENTIONAL MAGNETIC RESONANCE IMAGING METHODS

MRI has emerged as the leading modality for imaging of soft tissue structures around joints.^{3,4} One of the major advantages of MRI is the ability to manipulate contrast to highlight different tissue types. Common contrast mechanisms include two-dimensional (2D) multislice T1-weighted, proton-density-weighted, and T2-weighted imaging, all of which can be derived with or without fat suppression. Imaging hardware and software have developed considerably in recent years; improved gradients and RF coils, fast or turbo spin-echo imaging, and techniques such as water-only excitation provide significant advancements in the field of MRI.

Although tissue relaxation times and imaging parameters are the major determinants of contrast differences between different tissue types, lipid suppression increases contrast between nonlipid and lipid-containing tissues and affects how the MR scanner sets the overall dynamic range of the image. Fat saturation, in which fat spins are excited and then dephased before imaging, is the most common type of lipid suppression. Another type of lipid suppression that can selectively excite water-only spins is known as *spectral-spatial excitation*.⁵ Finally, in areas of magnetic field inhomogeneity, a technique called *inversion recovery* provides a way to suppress lipids that comes at the expense of SNR and contrast-to-noise ratios.

The type of contrast is critical for SNR and the visibility of pathologic processes. Although T2-weighted imaging creates contrast between short T2 tissues and synovial fluid, it does so at the expense of the MRI signal. High signal from fluid is useful to highlight defects such as fissuring or tears, yet variation in internal short T2 signal is poorly depicted. Also, T2-weighted scans are often 2D, leaving small slice gaps that may contain areas of tissue damage.

Another technique, three-dimensional spoiled gradient-recalled echo imaging with fat suppression (3D-SPGR), destroys or spoils the transverse magnetization between successive TRs. This method produces high cartilage signal but low signal from adjacent joint fluid. 3D-SPGR is the standard for quantitative morphologic imaging of cartilage.⁶ This technique is useful for cartilage volume and thickness measurements but does not adequately highlight surface defects with fluid and does not allow thorough evaluation of other joint structures such as ligaments or menisci.

MRI of joints requires close attention to spatial resolution. For example, to see early morphologic degenerative changes in cartilage, imaging with a resolution on the order of 0.2 to 0.4 mm is required.⁷ The ultimate resolution achievable is governed by the SNR possible within a given imaging time and system. Use of high field strength and dedicated phased-array or surface coils usually results in the best possible resolution *in vivo*. A high-resolution technique that provides both morphologic and physiologic data would be ideal in the evaluation of joints. Given current techniques, it is likely that a combination of a high-resolution morphologic imaging sequence with a sequence for evaluation of tissue physiology will be the most useful.

Two-dimensional fast spin-echo imaging

Conventional MRI of the musculoskeletal system is commonly performed with turbo or fast spin-echo (FSE) methods and is often limited to 2D multislice acquisitions obtained in multiple planes. These methods provide excellent SNR and contrast between tissues of interest but produce anisotropic voxels and slice gaps, which results in the inability to reformat the images into multiple oblique planes. For example, a typical sagittal image may have 0.3- to 0.6-mm in-plane resolution but a slice thickness of 2 to 5 mm. These methods provide excellent depiction of structures in the imaging plane, but evaluation of oblique or small structures across multiple slices can be challenging. For these reasons, 3D acquisitions with thin slices are more appealing.

Two-dimensional FSE methods are the primary clinical sequences used to image internal derangements of joints and show great ability to detect cartilage lesions (Fig. 41.4).⁸ They can also detect bone marrow edema,⁹ effusions, synovium,³ and ligament and meniscal tears.⁴ Several scoring systems for osteoarthritis, including Whole-Organ Magnetic Resonance Imaging Score (WORMS), Boston-Leeds Osteoarthritis Knee Scoring (BLOKS), and Knee Osteoarthritis Scoring System (KOSS),^{10,11} have been developed based on this acquisition method.

Bone marrow edema that corresponds to inflammation, seen in the early pathogenesis of inflammatory processes such as rheumatoid arthritis and ankylosing spondylitis, is best appreciated with MRI, especially fluid-sensitive T2-weighted FSE imaging. CT imaging, in comparison, is better for visualization of structural changes seen in later-stage pathologic processes.^{12,13}

Three-dimensional gradient-echo techniques

Three-dimensional MRI sequences are extremely valuable because they produce images with isotropic voxels that do not contain slice gaps. These characteristics allow the images to be reformatted into various oblique planes, which improves the visualization of the anatomy while shortening examination time. Traditional 3D gradient-recalled echo (3D-GRE) methods have the potential to acquire data with isotropic voxel sizes but suffer from a lack of contrast, especially compared with 2D spin-echo approaches. 3D-SPGR has demonstrated high accuracy for imaging cartilage lesions^{1,14,15}; however, it has two main disadvantages: (1) a lack of reliable contrast between tissue and fluid, and (2) long imaging times that may require up to 8 minutes. Due to the lack of reliable fluid sensitivity, 3D-GRE methods are less useful for diagnosis of ligament or meniscal tears than spin-echo techniques. Despite its limitations, 3D-SPGR is considered the standard for morphologic imaging of cartilage.⁶

The SPGR and GRE techniques can be combined with water-fat separation methods such as iterative decomposition of water and fat with echo asymmetry and least squares estimation (IDEAL) to produce excellent-quality water and fat images with high resolution (up to $0.3 \times 0.3 \times 1.0$ mm). The SPGR method suppresses signal from joint fluid, whereas the GRE method accentuates it (Fig. 41.5). Compared with balanced steady-state free precession (see later), these methods are less SNR efficient but also less sensitive to magnetic field inhomogeneity. Therefore, an ideal 3D cartilage imaging sequence that provides an optimal combination of resolution, SNR efficiency, and minimal artifacts has yet to be established. For this reason,

Fig. 41.4 Two-dimensional fast spin-echo magnetic resonance images for a patient with cartilage damage. (a) Sagittal proton-density image showing medial compartment cartilage loss (arrow). (b) Sagittal T2-weighted image with fat suppression showing the same medial compartment damage (arrow). (c) Coronal T1-weighted image showing medial compartment damage (arrow). Fluid is dark on this image. (d) Coronal T2-weighted image with fat suppression showing medial compartment damage (arrow).

a number of newer techniques have been developed to improve cartilage imaging.

ADVANCED MAGNETIC RESONANCE IMAGING TECHNIQUES

Dual-echo steady-state imaging

Dual-echo steady-state (DESS) imaging has proved useful for evaluation of cartilage morphology, for both volumetric and degradation assessment, because of its ability to maximize contrast between cartilage and synovial fluid.¹⁵ DESS acquires two or more gradient echoes separated by a refocusing pulse and then combines both echoes into the image. This results in an image with higher T2* weighting, which has bright signal from both cartilage and synovial fluid. This is currently the imaging method of choice for cartilage evaluation in the Osteoarthritis Initiative.¹⁴

Driven equilibrium Fourier transform imaging

Driven equilibrium Fourier transform (DEFT) imaging has been used in the past as a method of signal enhancement in spectroscopy.¹ DEFT imaging uses a 90-degree pulse to return magnetization to the z-axis, which increases signal from tissues with long T1 relaxation times such as synovial fluid. Unlike in conventional T1- or T2-weighted MRI, the contrast in DEFT imaging depends on the ratio of the T1 and T2 of a given tissue. For musculoskeletal imaging, the DEFT method produces contrast by enhancing the signal from synovial fluid, rather than attenuating the signal from cartilage as in T2-weighted sequences. This results in bright synovial fluid at short TR. At short TR, DEFT imaging shows much greater cartilage-fluid contrast than SPGR, proton-density FSE imaging, or T2-weighted FSE imaging.¹⁶ DEFT imaging has been combined with a 3D echoplanar readout to make it an efficient 3D cartilage imaging technique. Unlike in T2-weighted FSE, cartilage signal is preserved owing to the short TE. A high-resolution 3D data set of the entire knee using a 512×192 matrix, 14-cm field of view, and 3-mm slices can be acquired in about 6 minutes. Initial studies of cartilage morphology have been done using DEFT imaging,¹⁵ but this technique has not been conclusively proven to be superior to 2D approaches. A similar sequence, referred to as *DRIVE*, is FSE with driven equilibrium pulses and has also been used in musculoskeletal imaging.^{1,16}

Balanced steady-state free precession imaging

Balanced steady-state free precession (bSSFP) MRI is an efficient, high-signal method for obtaining 3D MR images.¹ Depending on the manufacturer of the MRI scanner, this method is also called *True-FISP* (Siemens, Malvern, Pa.), *Fiesta* (General Electric, Milwaukee), or *balanced FFE*

imaging (Phillips, Andover, Mass.).¹⁷ Advances in MR gradient hardware have made it possible to use bSSFP without experiencing the banding or off-resonance artifacts that were previously a problem. However, banding artifacts due to off-resonance are still an issue as TR increases or at 3.0 T. Hence, TR is usually kept below 10 ms, which limits the overall image resolution. Multiple-acquisition bSSFP can be used to achieve higher resolution at the cost of additional scan time.¹

Many methods have been proposed to provide fat suppression with bSSFP imaging. With a sufficiently short TR and homogenous magnetic field, conventional fat suppression or water-excitation pulses can be used.¹⁸ Linear combinations of bSSFP¹⁹ and fluctuating equilibrium MRI (FEMR)²⁰ use the frequency difference between fat and water and multiple acquisitions to separate fat and water. Intermittent fat suppression uses transient fat saturation pulses to suppress lipid signal.²¹ IDEAL uses multiple acquisitions to separate fat and water but does not depend on the fat-water frequency difference to constrain the TR.²² Rapid separation of water and fat can be achieved with phase detection.²³

Several studies have demonstrated the usefulness of bSSFP articular cartilage and musculoskeletal imaging.²⁴ Because of the bright synovial fluid and 3D nature of the acquisition, bSSFP is also effective for imaging internal derangements of ligaments and menisci, which makes it more generally useful than SPGR. Vastly interpolated projection reconstruction imaging (VIPR), a variant of bSSFP, has been shown to be useful in imaging the cartilage, ligaments, and menisci in a rapid manner with isotropic resolution (Fig. 41.6).²⁵

Three-dimensional fast spin-echo imaging

Two-dimensional FSE imaging is a powerful clinical tool but suffers from anisotropic voxels, slice gaps, and partial volume effects. 3D acquisitions with FSE were applied in brain imaging several years ago.²⁶ 3D FSE, with flip angle modulation to reduce blurring and parallel imaging to reduce imaging time, has made isotropic imaging with spin-echo contrast a clinical reality.^{26,27} Preliminary studies demonstrating the effectiveness of using 3D FSE with isotropic resolution in the knee,²⁶ ankle,²⁸ and wrist²⁹ have been promising; however, additional studies are warranted before these sequences replace 2D FSE. 3D FSE imaging shows isotropic resolution with the ability to obtain high-quality multiplanar reformatted images (Fig. 41.7).

High-field magnetic resonance imaging

Several centers currently have 7.0-T human MRI systems available for research purposes. Although these systems suffer from RF penetration and high-power deposition problems, they have a considerable SNR advantage over lower-field systems.³⁰ These systems are able to get to a higher resolution in a shorter period of time and may be useful for showing tissue ultrastructure. Figure 41.8 shows a representative 7.0-T data set.

Fig. 41.6 Vastly interpolated projection reconstruction balanced steady-state free precession images of the knee at 3.0 T for a healthy volunteer. This technique produces isotropic 0.4-mm resolution across the knee, which allows reformatted images in any imaging plane. Scan time was only 5 minutes. (a) Coronal image, 2-mm section thickness. (b) Sagittal reformatted image, 2-mm section thickness. (c) Axial reformatted image, 2-mm section thickness. (Courtesy W. Block, University of Wisconsin, Madison.)

Fig. 41.7 Three-dimensional fast spin-echo imaging using flip angle modulation and parallel imaging. This acquisition was done at 3.0 T with an imaging time of 5 minutes and an isotropic 0.6-mm resolution. (a) Coronal image, 2-mm section thickness. (b) Sagittal reformatted image, 2-mm section thickness.

Fig. 41.8 Sagittal image for a healthy volunteer at 7.0 T using a three-dimensional spoiled gradient-echo method. Excellent signal-to-noise ratio was achieved with a resolution of $0.3 \times 0.3 \times 1.0$ mm in 3 minutes. (Courtesy R. Regatte, New York University.)

Cartilage thickness and volume mapping

Measurement of cartilage thickness and volume can be useful in tracking osteoarthritis. The Osteoarthritis Initiative uses high-resolution 3D imaging and manual or semi-automated segmentation of images to demonstrate that changes in cartilage thickness can be visualized in high-risk populations in as short a time as 1 year.³¹ Figure 41.9 shows a 3D reconstruction of knee cartilage from MRI data.

Magnetic resonance imaging to demonstrate physiologic activity

Contrast-enhanced imaging

Intravenous contrast agents used in MRI often contain gadolinium coupled to a large molecule to prevent toxicity. These agents reduce the T1 relaxation time of vascular tissue and areas of enhancement appear bright on T1-weighted images. These images are often acquired with fat suppression to improve the dynamic range and conspicuity of the enhancing tissues. This technique is especially useful in inflammatory arthritis because synovium and pannus are quite vascular and show considerable contrast enhancement (Fig. 41.10). This method can be used to track synovitis in osteoarthritis as well as the activity of drugs for inflammatory arthropathies.³²

T2 relaxation time mapping

The T2 relaxation time is a function of both the water content and collagen ultrastructure of the tissue. Measurement of the spatial distribution of the

T2 relaxation time may reveal areas of increased or decreased water content, correlating with tissue damage. To measure the T2 relaxation time with a high degree of accuracy, attention must be paid to the MR technique. Typically, a multiecho spin-echo technique is used, and signal levels are fitted to one or more decaying exponentials, depending on whether it is believed that there is more than one distribution of T2 within the sample.³³ However, for TEs used in conventional MRI, a single exponential fit is adequate. An image of the T2 relaxation time is then generated with either a color or a gray-scale map representing the relaxation time, as shown in Figure 41.11.

When the spatial distribution of T2 relaxation times within articular cartilage is investigated, aging appears to be associated with a T2 relaxation time increase in the transitional zone,³⁴ whereas relaxation times have been shown to be anisotropic with respect to orientation in the main magnetic field.³⁵ Focal increases in T2 relaxation times within cartilage have been associated with matrix damage, particularly loss of collagen integrity. Studies on T2 relaxation times documenting the effects of age,³⁴ gender,³⁶ and activity³⁷ have also been published. T2 relaxation time measurements also may be useful in characterizing the state of fibrocartilage tissues such as the menisci and ligaments.³⁸

Fig. 41.9 Three-dimensional volume rendering of knee cartilage from segmented high-resolution magnetic resonance imaging. Segmentation allows quantitative measurements of thickness and volume.

T1rho mapping

T1rho imaging, which involves the relaxation of spins under the influence of an RF field, is a promising technique for evaluating cartilage and other tissues.³⁹ T1rho imaging is useful because it may be sensitive to early proteoglycan depletion.^{39,40} In T1rho imaging the magnetization is tipped into the transverse plane and “spin locked” by a constant RF field. Recent advances in T1rho imaging have led to rapid cartesian acquisition strategies for use at 3.0 T.^{41,42} An example of a T1rho map for a healthy volunteer is shown in Figure 41.11. T1rho imaging has also been shown to be useful in detection of early meniscal and cartilage lesions.^{43,44}

Delayed contrast-enhanced imaging

Negatively charged Magnevist or Gd-DTPA2⁻ (Berlex, Richmond, Calif.), is a common MRI contrast agent. After intravenous injection, Gd-DTPA2⁻ penetrates into cartilage and concentrates where glycosaminoglycan (GAG) content is relatively low. Subsequent T1 imaging (which is reflective of Gd-DTPA2⁻ concentration) therefore yields an image depicting GAG distribution. This technique is referred to as *delayed gadolinium-enhanced MRI of cartilage* (dGEMRIC), with the “delay” referring to the time needed for Gd-DTPA2⁻ penetration and distribution.⁴⁵ A T1 map allows assessment of GAG content, with lower values corresponding to areas of GAG depletion.

Various clinical cross-sectional studies in specified populations have provided much insight. One study reported that individuals who regularly exercise have higher dGEMRIC indices than individuals who are sedentary. In a relatively large study of patients with hip dysplasia, measures of the severity of dysplasia (the radiographically determined lateral center edge angle) and pain both correlated with dGEMRIC indices but not with the standard radiologic parameter of joint space narrowing. In another study, lesions in patients with osteoarthritis were more apparent with the dGEMRIC technique than with standard MRI scans.⁴⁶ Additionally, dGEMRIC findings have been correlated with Kellgren and Lawrence radiographic grading of osteoarthritis.⁴⁷ Combining dGEMRIC methods with T2 mapping requires careful attention to technique.⁴⁷ It is important to note that, as a free ion, Gd-DTPA2⁻ can be toxic; however, Gd-DTPA2⁻ contrast agents approved by the U.S. Food and Drug Administration are chelated, which greatly reduces their toxicity. Patients with renal insufficiency or dysfunction should avoid imaging using this contrast agent.⁴⁸

Physiologic methods like dGEMRIC and T2 mapping can be time consuming and difficult to perform on a routine basis. dGEMRIC is often performed using a variable flip angle 3D-SPGR approach, as shown in Figure 41.12.^{47,49} SSFP methods also show promise in improving the speed and SNR of T1 and T2 relaxation time measurements.⁵⁰

Sodium magnetic resonance imaging

Because sodium-23 (²³Na) has an odd number of protons and/or neutrons it possesses a net nuclear spin and can exhibit the MR phenomenon. ²³Na

Fig. 41.10 Coronal magnetic resonance images of the wrist for a patient with rheumatoid arthritis. (a) T1-weighted image shows bone erosions as areas of signal loss in the marrow fat. (b) Contrast-enhanced image of the wrist shows brightly enhancing synovium and pannus.

Fig. 41.11 Measurements of tissue physiology with magnetic resonance imaging T2 map (left) and T1rho map (right) of the tibial cartilage in a healthy volunteer. The color scale shows relative relaxation time values between 0 and 100 ms. Changes in T2 relaxation time are correlated with collagen matrix status; changes in T1rho are correlated with proteoglycan content.

Fig. 41.12 Delayed gadolinium-enhanced magnetic resonance imaging of cartilage in a healthy volunteer. The left image is a spoiled gradient-echo image used to map the T1 relaxation times. The right image is a T1 relaxation time map with a gray scale from 0 to 3000 ms.

MRI has been shown to be useful in musculoskeletal imaging owing to the natural abundance of sodium in articular cartilage. As a result of the opposing charges associated with sodium and GAG, ^{23}Na MRI can be used to estimate the GAG content in cartilage. Although it is both accurate and noninvasive, ^{23}Na MRI requires high-field MRI systems (3.0 or 7.0 T). The concentration of ^{23}Na in normal human cartilage is about 320 μM , with T2 relaxation times between 2 and 10 ms.⁵¹ The combination of lower resonant frequency, lower concentration, and shorter T2 relaxation times compared with ^1H make *in vivo* imaging of ^{23}Na challenging. The use of ^{23}Na MRI is limited because special transmit and receive coils and relatively long imaging times are required to achieve adequate SNR.

^{23}Na MRI has shown promising results in the imaging of articular cartilage due to its ability to depict regions of proteoglycan depletion.⁵¹ The ^{23}Na atoms are associated with the high fixed-charge density present in proteoglycan sulfate and carboxylate groups. Some spatial variation in ^{23}Na concentration is present within normal cartilage.⁵¹ Because of the short T2 relaxation times of sodium, imaging is often done with a non-cartesian trajectory.⁵² Figure 41.13 shows proton and sodium images from a patient with a prior ligament injury. In cartilage samples, sodium imaging has also been shown to be sensitive to small changes in proteoglycan concentration.⁵³ It is sensitive to early decreases in proteoglycan concentration in osteoarthritis and can be even more sensitive to early changes when triple-quantum-filtered imaging is used.⁵⁴

CONCLUSION

MRI is a powerful tool for the imaging and understanding of musculoskeletal tissue. Improvements have been made in morphologic imaging of joints in terms of contrast, resolution, and acquisition time. This allows for the development of detailed tissue maps and provides the ability to quantify both thickness and volume. Much progress has been made in the imaging of joint physiology. Important areas include the detection of changes in proteoglycan content and collagen ultrastructure in cartilage and other tissues.

The choice of a particular MRI protocol for joint imaging is strongly dependent on patient factors. For many patients with internal derangement, imaging with standard FSE and/or 3D-SPGR sequences may suffice. For patients being considered for surgical or pharmacologic therapy, a more detailed evaluation may be required. For example, fast morphologic imaging along with evaluation of cartilage physiology may allow for noninvasive evaluation of cartilage implants at different time points.

Current musculoskeletal MRI protocols include multiple planes of 2D-FSE and 3D-GRE images. The new morphologic methods presented here such as VIPR, 3D-FSE, and bSSFP achieve isotropic resolution for an entire joint in a single acquisition, which decreases scan time. The isotropic data can then be reformatted into standard or oblique planes using slice averaging to improve SNR. Combining these methods with fat-water

Fig. 41.13 Proton and sodium magnetic resonance images of the knee of a patient 3 years after anterior cruciate ligament injury. The proton image (a) shows intact articular cartilage. The sodium concentration measured at 3.0 T is overlaid on the proton image as a heat scale (b). An area of decreased sodium is seen in the trochlea cartilage, which may represent an area of proteoglycan depletion.

separation methods, such as IDEAL, provides water, fat, and combined images, which has various advantages.

Additional studies are required to validate the sensitivity of these isotropic methods in detecting common joint disorders such as meniscal tears. Isotropic acquisitions could improve patient throughput or allow detailed studies of tissue physiology when used in combination with T2 mapping,

T1rho mapping, or sodium MR methods. The integration of fast, high-resolution morphologic imaging methods with newer physiologic techniques has the potential to expand the sensitivity of MRI to early cartilage degeneration. Ideally, the combination of these techniques will lead to an MRI examination that is brief, is well tolerated, and contains both morphologic and physiologic data.

Musculoskeletal ultrasound

■ DAVID KANE

- Musculoskeletal ultrasound is an established tool in rheumatologic practice.
- Ultrasound performed in clinic provides immediate diagnosis and objective measures of rheumatologic disease.
- Ultrasound applications in rheumatology extend beyond the joint to many different tissues involved in rheumatologic disease (e.g., nerves, blood vessels, salivary glands).
- Ultrasound can guide interventions such as joint and soft tissue aspiration and injection, nerve blocks, and synovial biopsy.

INTRODUCTION

Musculoskeletal ultrasound imaging is now an established diagnostic technique for all clinicians who manage musculoskeletal disease. Over the past two decades, rheumatologists have pioneered the introduction of ultrasound directly into rheumatology clinics, thus exploiting the immediate diagnostic potential of this technique.¹ Aided by the development of high-frequency transducers, reduced equipment costs, and a better understanding of pathologic features as revealed by musculoskeletal ultrasound, there has been a rapid international adoption of this technology by rheumatologists. Ultrasound is now a compulsory part of specialist rheumatology training in some European countries, and training guidelines have been published by the European League Against Rheumatism (EULAR)² and the Pan-American League Against Rheumatism (PANLAR)³ with ultrasound courses now being run in most countries in which rheumatology is practiced.

The principal reason that ultrasound has become an increasingly useful tool in rheumatology is that it can be directly performed by the rheumatologist as an extension of the clinical examination^{4,5} (Fig. 42.1). This is in contrast to other imaging modalities such as magnetic resonance imaging (MRI), scintigraphy, and computed tomography (CT), which are performed remote to the clinical evaluation. Ultrasound is a high-definition imaging technique that can simultaneously image soft tissues and bone, producing multiplanar real-time dynamic images without exposing the patient to ionizing radiation. Although it is safe, inexpensive, and highly acceptable to patients, ultrasound should always be selected in the context of all imaging modalities available to the rheumatologist.⁵ Ultrasound has poor penetration of deep musculoskeletal tissue and cannot image the internal structures of bones; thus MRI and CT scanning are much more suitable for indications such as evaluation of internal and bony structures, deep-lying joints, and spinal structures.

MUSCULOSKELETAL ULTRASOUND IMAGING

Basic principles of ultrasound

Musculoskeletal ultrasound produces images of soft tissues through emission of high-frequency sound waves from an ultrasound transducer.⁶ For optimal musculoskeletal imaging, these frequencies range from 5 to 18 MHz and are inaudible to the human ear. Ultrasound waves travel through different soft tissues at different speeds based on the propagation speed of that tissue. The propagation speed depends on the density of the tissue but also on the number of internal reflective structures, for example, tendon fibers,

which absorb or reflect the sound wave energy. The transducer also acts as a receiver for the reflected sound waves. In brief, less dense structures such as fluid that lack tissue interfaces will appear as dark or hypoechoic, whereas more dense structures with multiple interfaces such as tendon will appear as brighter or hyperechoic. The tissue interfaces also produce typical features of a tissue, such as the regular parallel lines of a tendon or ligament, which aid in their identification.

Ultrasound can be used to determine tissue movement—such as blood flow—based on the Doppler principle.⁷ This principle dictates that sound waves increase in frequency when they reflect from objects that are moving toward the transducer and decrease in frequency when they reflect from objects moving away from the transducer. There are two main types of Doppler ultrasound: color flow Doppler (CFD) and power Doppler (PD). CFD represents an estimate of the mean Doppler frequency shift and relates to the velocity and direction of red blood cells. This allows CFD to determine direction of blood flow, with blood flow moving toward the transducer indicated as a red signal and blood flow moving away from the transducer indicated as a blue signal. CFD is best suited for evaluation of high-velocity flow in large vessels. PD measures the amplitude of the Doppler signal without directional information. Both PD and CFD produce color images of blood flow superimposed on the gray-scale ultrasound image. In assessing tissues for Doppler signal, it is critical first to obtain an adequate, well-orientated gray-scale image of the area of interest before evaluation with Doppler imaging. Otherwise, normal vascular structures around joints may be erroneously diagnosed as inflammatory tissue within the joint.

Because PD has increased sensitivity to low-volume, low-velocity blood flow, it has been particularly useful for measuring blood flow associated with soft tissue inflammation in joints and other musculoskeletal tissues. Additionally, the PD signal in a standard reference gray-scale image can be scored on a semiquantitative scale of 0 to 3 or a quantitative scale based on the number of colored pixels in a region of interest.⁸ This has a potential advantage when monitoring inflammatory changes in joints in response to therapy. Recent advances in CFD imaging technology have improved sensitivity for the detection of soft tissue inflammation, and PD and CFD now approach similar levels of sensitivity for detection of synovitis.

Ultrasound equipment

Inadequate ultrasound equipment leads to inadequate musculoskeletal ultrasound imaging. In selecting equipment, one can choose from a wide variety of available equipment ranging from larger, less mobile, high-definition systems to smaller, portable systems.⁹ In general, the price of ultrasound equipment is inversely proportional to the size of the equipment and directly proportional to the quality of the image. Portability is an attractive feature for those who require mobility at different clinics and at the bedside but increases the cost of the equipment. The minimum requirements are a linear-array high-frequency transducer capable of imaging larger, deeper joints (range of frequency is 5 to 10 MHz) but also capable of imaging small superficial structures such as tendons and nerves (range of frequency is 10 to 15 or even 20 MHz).

Color and power Doppler imaging options are an essential requirement for musculoskeletal ultrasound imaging. In combination with the high-frequency linear-array transducer, the ultrasound system should have a dedicated musculoskeletal software package. Additional software options such as an extended field of view, elastography, three-dimensional capabilities, and contrast capability are playing a growing role in musculoskeletal ultrasound but are not essential for routine practice.

Consideration should be given to how the ultrasound examination results will be archived, and additional software for picture archiving may

Fig. 42.1 Ultrasound of the foot and ankle in the rheumatology clinic. After history taking and physical examination the rheumatologist can immediately apply the ultrasound probe directly to the symptomatic anatomic area on the foot and ankle, which allows immediate confirmation of the clinical diagnosis and prescription of therapy. The panel of images shows multiple probe positions and corresponding ultrasound images demonstrating the flexibility of this technique.

be required. It is important to consider the environment in which the ultrasound examination will be performed and to ensure good ventilation or air conditioning and the availability of an adjustable-height examination couch and chair for the operator to optimize the ergonomics of the work environment of the ultrasonographer.

Education and training

Enthusiasm for ultrasound in rheumatology has been tempered by the realization that this is an operator-dependent technique which requires a significant period of technical skills training.¹⁰ Although there has been a considerable increase in the number of rheumatologists practicing musculoskeletal ultrasound, there still are barriers related principally to access to equipment and access to trainers and training. Most national and international ultrasound societies now provide short intensive ultrasound courses for rheumatologists. EULAR has been at the forefront of musculoskeletal ultrasound education and was the first to establish a system of basic, intermediate, and advanced ultrasound courses and to have published guidelines on standardized images, curriculum, and training.² The American College of Rheumatology⁵ and PANLAR³ have now also published guidelines and organized courses, and national societies in countries such as Germany and Italy have incorporated ultrasound into the training curriculum for rheumatologists.¹¹

All of these guidelines recognize that the trainee must undertake a significant period of scanning practice to acquire the appropriate technical skills. Formal short courses, textbooks, and Internet-based educational aids

are useful adjuncts to training but do not substitute for continuous interactive learning with an experienced mentor. There is no consensus yet on competency or competency assessment in musculoskeletal ultrasound. Although performing a quantity of ultrasound scans ranging from 250 to 500 is estimated to be equivalent to an adequate period of training by the various guidelines, evaluation of competency should include a practical qualitative assessment. It is recommended that all ultrasonographers keep a log book of ultrasound scans for validation of training. There is a need for an internationally recognized competency qualification in ultrasound in rheumatology both to consolidate and to develop this subspecialty interest.

Standard views and artifacts

Ultrasound imaging is a dynamic technique performed in multiple planes in real time. A number of standard imaging planes have been described for peripheral joints to orientate the examiner and also to provide ease of reference and comparison of ultrasound scans performed at different times.¹² All ultrasound scans are defined by two perpendicular views: transverse (short axis) and longitudinal (long axis). All pathologic processes should be confirmed and fully described in two perpendicular views. Most ultrasound systems now have predetermined settings for different-sized joints and soft tissues, although the operator may adjust other technical features such as contrast, brightness, and sharpness using image-processing software to optimize the image. It is important for the operator to have a technical knowledge of specific frequency, gain and software settings to optimize imaging

depending on the tissue examined. Each ultrasound system has different applications for this and further information should be provided by the system manufacturer.

Artifacts are ultrasound echoes that do not correspond to the real imaging target in either distance or direction.¹³ Although these can cause confusion in the interpretation of the image, a number of standard artifacts can be an invaluable aid in identifying soft tissue landmarks and pathologic processes.

Anisotropy

Anisotropy is the most common artifact observed in musculoskeletal tissues and is extremely valuable in identifying structures such as tendons (Fig. 42.2, Video 42.1). Anisotropy occurs when the angle of the ultrasound beam is not perpendicular to the tissue being scanned. This causes the sound waves to be scattered rather than reflected back to the transducer/receiver; this results in loss of signal, which is presented as a hypoechoic area in linear structures such as tendons. Although this can result in an inaccurate diagnosis of tendon lesions such as tendinosis or tendon tears, the operator

learns to change the angle of the ultrasound transducer to a perpendicular plane and thus eliminate the artifact. In deeper or dense tissues, this technique can also allow identification of small tendon structures through the ability to change them from hyperechoic to hypoechoic structures with slight angulation of the probes.

Refractile shadowing/edge artifact

When the ultrasound beam hits a structure at an oblique angle (e.g., edge of a tendon in transverse view), a hypoechoic area can occur at the edge of the hyperechoic structure. This can erroneously be interpreted as fluid or tendon sheath thickening (Fig. 42.3c).

Acoustic shadowing

Acoustic shadowing occurs when an ultrasound beam hits a highly reflective surface such as bone or calcified tissues and there is a failure of echo return from the tissues beneath the reflected surface with consequent loss of signal. The appearance is of a hyperechoic reflection with little or no signal distal to it (see Fig. 42.3b).

Fig. 42.2 Anisotropy. (a) The transducer is placed perpendicular to the flexor tendon in the anatomic hand model. (b) The corresponding ultrasound plane in a normal subject shows the tendon as hyperechoic and homogeneous. (c) The transducer is placed at an acute angle to the flexor tendon in the anatomic hand model. This angulation causes anisotropy when imaging the tendon. (d) The corresponding ultrasound plane in a normal subject shows the tendon as hypoechoic and heterogeneous.

Fig. 42.3 Common ultrasound artifacts. (a) Plain radiograph for a patient with systemic lupus erythematosus showing subcutaneous calcification on the ulnar aspect of the elbow. (b) The corresponding ultrasound image shows the edge of the area of calcification with hyperechoic calcified tissue (arrows) with acoustic shadowing deep to the calcified tissue on the left and normal skin, subcutaneous tissue, and muscle on the right-hand side. (c) Beam edge artifact caused by refractile shadowing at the side of a flexor tendon gives a hypoechoic appearance and can be mistaken for tendon sheath thickening or fluid. (d) “Comet tail” appearance of a needle in muscle tissue is a reverberation artifact.

Acoustic enhancement

As the ultrasound beam travels through an increasing depth, the intensity of the echoes returned to the transducer decreases; however, should the beam encounter a fluid collection, there is enhanced transmission of sound waves through the fluid, which leads to a brighter signal in the tissues distal to the fluid collection. This can be mistaken for an integral change in the tissue structure.

Reverberation

Reverberation of image occurs when an ultrasound beam encounters highly reflective surfaces, which leads to multiple reflective echoes. The most typical example of this is the “comet tail” artifact, such as is produced by a needle (see Fig. 42.3d, Video 42.2). The presence of this artifact can be of use in interventional procedures in identifying the needle tip. Similar metal artifacts are observed with joint prostheses.

Power Doppler scanning technique artifacts

Before assessment for Doppler imaging, it is critically important that the operator obtain a reference gray-scale image with the tissue motionless. Then any Doppler signal detected can be attributed to a specific anatomic region being examined and is not due to transducer, operator, or tissue movement. An inexperienced operator can exert undue pressure on the soft tissues to obtain this fixed image, thus obliterating small-vessel blood flow and giving a false-negative PD signal.

Doppler imaging artifacts

An extensive description of the artifacts that occur with Doppler imaging has been presented by Torp-Pederson and Terslev.⁷ These include (1) random noise, which is caused by setting the color gain too high; (2) mirror artifact, in which Doppler flow can be seen beneath the bone surface as well as above; (3) aliasing, which occurs with CFD but not with PD; and (4) blooming, in which the pictorial representation of the vessel flow expands beyond the vessel wall, which is also caused by oversetting of the gain. In practice, it is advisable to adjust the pulse repetition frequency to the point at which there is no vessel signal below bony cortex and then to adjust the gain until random-noise Doppler artifacts disappear.

MUSCULOSKELETAL ULTRASOUND IN RHEUMATOLOGY

Synovial tissue and the synovial joint

The application of ultrasound in the diagnosis of rheumatoid arthritis (RA) not only has aided in more rapid diagnosis of disease but also has provided novel insights into the pathologic processes in RA.¹⁴ Ultrasound has consistently been proven to demonstrate synovial fluid effusion and synovial thickening with a greater sensitivity than clinical examination. This has been confirmed in both small and large joints, and the OMERACT/EULAR Ultrasound Task Force has published definitions of these pathologic findings that will aid in the standardization of ultrasound diagnosis and the development of ultrasound findings as an outcome measure in RA.¹⁵

Synovitis is a term used to refer to joint inflammation seen on ultrasound, which appears as joint effusion, synovial thickening, or a combination of both. Joint effusion is observed as an anechoic or hypoechoic area within the capsule of the joint that is compressible and displaceable but does not have a PD signal. Synovial thickening is diagnosed by the presence of abnormally thickened hypoechoic tissue within the joint capsule that is partially compressible but not displaceable and that may demonstrate PD signal. Ultrasound has demonstrated subclinical synovitis in both early disease and late disease, and in patients in remission.¹⁶ The relevance of subclinical synovitis seen on ultrasound remains controversial and challenges the concept of defining both diagnosis and prognosis based on the number of clinically inflamed joints. In one study, up to a third of cases of clinically diagnosed oligoarthritis were redefined by ultrasound assessment as polyarthritis, which has a potentially worse prognosis.¹⁷ In patients in remission, subclinical synovitis detected by ultrasound and MRI correlated with progressive radiologic damage, which confirms that it is a relevant finding.¹⁸

Doppler ultrasound examination is a standard part of the assessment for synovial joint inflammation. PD is most sensitive in small and superficial joint structures, with less PD signal demonstrated in deeper joints such as the hip and shoulder. PD shows blood flow within the synovial tissue, which is due to a combination of angiogenesis and vasodilatation. Both these processes are important components of the chronic inflammation of the synovial joints. PD can detect blood flow even within some normal joints, has

been demonstrated to have sensitivity and specificity comparable to those of MRI,⁸ and has been validated through correlation with the findings of synovial histopathologic analysis. PD semiquantitative scoring has been developed and shows good intraobserver and interobserver reproducibility. This allows for the quantification of PD signal in joints before and after therapy. A number of studies have also indicated that PD findings may have a predictive and prognostic value. Studies of patients in remission confirmed that persistent PD signal correlated with the development of joint damage.¹⁸ In another study of patients with established RA, time-integrated assessment of PD ultrasound results demonstrated a strong correlation with damage progression on plain radiographs. This assessment was demonstrated to be superior to clinical and laboratory parameters.¹⁹

A number of studies have examined whether it is necessary to study all joints or only a subset of synovial joints in RA to assess disease activity objectively by ultrasound.²⁰ Given the time required to image multiple joints, scanning of a more limited but representative subset of joints would provide a more practical means of evaluation. Backhaus and colleagues²⁰ have reported that a panel of seven areas assessed by ultrasound (US7 score) provided a highly reproducible score that correlated well with other clinical and laboratory parameters of disease activity. Naredo and colleagues^{20a} performed a study developing a 12-joint score for RA. Further studies are being undertaken to see whether a limited subset of ultrasound images in RA patients can provide a more objective evaluation of disease activity than current clinical and laboratory scores.

Ultrasound-determined synovitis has the same characteristic imaging appearance in RA and in seronegative arthritis and cannot reliably differentiate the two diseases. In osteoarthritis, ultrasound studies have shown synovial inflammation features—including effusion, synovial thickening, and increased PD signal—in almost half of osteoarthritic knee and interphalangeal joints.²¹ The degree of synovial inflammation is less than that seen in RA, and PD signal is less frequently observed, being present in only 10% of interphalangeal joints. Ultrasound-determined synovial inflammation in hand osteoarthritis did not correlate with hand symptoms or with symptomatic response to treatment with methylprednisolone (Fig. 42.4, Video 42.3).²²

Tendon and enthesis

Ultrasound imaging of the tendon in inflammatory disease demonstrates the early changes of tendonitis as hypoechoic thickening of the tendon with widening of the spacing of the regular fibrillar infrastructure.²³ Tenosynovitis is seen as hypoechoic synovial tendon sheath thickening, which may consist of both hypoechoic tissue and fluid. PD signal is not normally seen in tendons but is observed in association with tendon inflammation. Later stages of tendon disease may show the progression of more circumscribed, hypoechoic foci in the tendon with gradual degeneration of the tendon, potentially culminating in tears (Fig. 42.5).

In the rheumatoid hand, flexor and extensor tendon involvement has been observed on ultrasound in up to 90% of cases in early RA and 100% of cases in established RA. In the wrist, the flexor carpi ulnaris tendon is most commonly involved in the early stage of RA, but ultimately any of the flexor or extensor tendons can become affected by the disease. In comparative studies of rheumatoid hand disease, MRI has been shown to be superior to ultrasound in detection of joint synovitis and erosion, whereas ultrasound has a higher sensitivity for the detection of tendon abnormalities. Standardized definitions now exist for tendon pathologic processes, and a validated scoring system for tenosynovitis is in development.²³ The options are to present quantitative measurements of the tendons and tendon sheath at fixed bony points in joints or to rely on a semiquantitative scoring system using standard EULAR reference images of tendons overlying joints. Some literature has focused on the size of tendons as an aid to the diagnosis of tendon abnormalities. A key limitation of this approach is that the size of the tendon also depends on the size of the individual, and it is important always to compare with the tendon on the opposite side in the patient, particularly if the tendon is asymptomatic.

In spondyloarthritis, ultrasound has been consistently demonstrated to be superior to clinical examination in the detection of tendon and enthesis inflammation.²⁴ This is of important diagnostic usefulness, because the clinical detection of enthesitis is one of the key features in the diagnosis of spondyloarthritis (Fig. 42.6). Although enthesitis is a cardinal feature of spondyloarthritis, it may also be found in situations such as mechanical stress and diseases such as gout. Thus it is important for the ultrasonographer to limit his or her reports to anatomic detail of sites rather than making diagnostic inferences. An additional advantage of ultrasound is that the bony surface of the tendon insertion can also be examined; this allows the identification of erosions and vascular changes, which are more typical in

Fig. 42.4 (a) Patient with puffy fingers and arthralgia. (b) Technique of performing an ultrasound examination on a metacarpophalangeal joint. The dorsal longitudinal plane is shown. (c) Marked gray-scale synovitis is demonstrated (arrows) in longitudinal view. There are also marked Doppler signals within the synovium. MC, metacarpal head; P, phalanx.

Fig. 42.5 Achilles tendinopathy. (a) Panoramic longitudinal view of the Achilles tendon shows hypoechoic thickening of the tendon distal to the calcaneal insertion. (b) Power Doppler signal is increased in the Achilles tendon, which confirms hypervascularity. Histologic studies show very little inflammatory infiltrate in this condition.

inflammatory disease than in mechanical stress. Associated bursitis and underlying joint synovitis can also be assessed at the same examination, which highlights the usefulness of ultrasound in the clinic.

Ultrasound can be used to monitor tenosynovitis and enthesitis and provides an objective score for assessing the effects of therapy. The Glasgow

Ultrasound Enthesitis Scoring System (GUESS) produces a combined score for gray-scale ultrasound features at entheses commonly involved in spondyloarthritis.²⁴ A four-point semiquantitative score based on gray-scale and PD features of tenosynovitis in hand, wrist, and ankle tendons in RA has been described and has moderate interobserver reliability.²⁵

Fig. 42.6 Achilles enthesitis. (a) Acutely painful posterior heel on right in a young man with a 6-week history of diarrhea and weight loss secondary to underlying Crohn disease. (b) Longitudinal ultrasound section through the Achilles tendon. There is bony irregularity of the calcaneum (straight arrows), hypoechoogenicity, loss of fibrillar pattern of the tendon at the bony insertion (curved arrows), and increased power Doppler signal in the region of the retrocalcaneal bursa (asterisk).

Dactylitis

Dactylitis is a characteristic sausage-shaped swelling of the toes or fingers seen in spondyloarthritis and most typically in psoriatic arthritis. Ultrasound has confirmed that the principal components of dactylitis are flexor tenosynovitis and increased subcutaneous soft tissue swelling.²⁶ One study of dactylitis in more established disease has also highlighted the need to consider underlying joint involvement, which can be masked by the degree of soft tissue swelling.²⁷ An interesting feature of dactylitis is that an equivalent degree of flexor tenosynovitis seen on ultrasound in RA does not provoke the same degree of exuberant adjacent soft tissue swelling seen in spondyloarthritis.

Muscle

In myositis, ultrasound demonstrates initial hypoechoic edema in inflamed areas of muscle. With marked perimysial edema, the hypoechoic fluid surrounding the muscle fibers can by contrast make the fibers appear hyperechoic. Hypervascularity is also seen on Doppler studies of inflamed muscle. In later stages of disease, muscle fiber atrophy and hyperechoic fat infiltration are observed. MRI is generally preferred for diagnostic imaging of the muscle in myositis because it is more sensitive for muscle edema. Ultrasound findings correlate well with MRI findings in myositis, and ultrasound may be an alternative to MRI for the diagnosis of myositis; however, more standardization needs to be done on the ultrasound definition of myositis (Fig. 42.7).²⁸

Ultrasound can readily demonstrate hypoechoic grade 2 and 3 muscle fiber tears and associated fluid in partial or complete muscle rupture. The targeted nature of ultrasound examination and the possibility for muscles to be contracted and relaxed during examination improve the sensitivity of ultrasound in the detection of tears, but MRI is superior in the detection of grade 1 tears, in which there may be only subtle edema. On the other hand, large amounts of muscle edema on MRI can obscure other structural abnormalities in larger tears. Ultrasound is very sensitive to calcific changes in tissues such as occur with myositis ossificans.²⁹

Bone erosion and osteophyte

Because of its highly reflective nature, bone has generally been considered an obstacle to ultrasound imaging. One advantage of the highly reflective signals produced by bone cortex is that bone surface changes in rheumatologic disease can be readily identified.

An *erosion* is defined as a clear cortical break visualized in two perpendicular planes at a site not associated with a nutrient foramen. Studies have

Fig. 42.7 Inclusion body myositis. (a) Transverse view of anterior mid-thigh shows hypoechoic atrophic quadriceps femoris (asterisks). (b) Transverse view in normal subject. (c) Longitudinal view of anterior mid-thigh shows hypoechoic and atrophic quadriceps femoris (asterisks). (d) Longitudinal view in normal subject.

compared ultrasound with conventional radiography, CT, and MRI in the diagnosis of joint erosions. Both ultrasound and MRI have been found consistently to be superior to plain radiography in detecting erosions, particularly in early RA.^{16,20} One particular advantage of MRI is that it has the ability to identify changes within the bone that may precede cortical breaks. Both MRI and ultrasound also can demonstrate synovial thickening and inflammation associated with the erosion; this gives rise to the concept of an “active erosion,” which cannot be distinguished on radiograph (Fig. 42.8, Video 42.4).

A limitation of ultrasound in the detection of bone erosion is that some joints such as the wrist carpal bones and the third and fourth metacarpophalangeal joints present only a limited part of their bony surfaces to an ultrasound probe, which reduces sensitivity in detecting erosions. Despite the increased sensitivity of ultrasound in the diagnosis of joint erosions, most rheumatologists continue to use plain radiographs to assess interval changes in joint damage. This is because radiographic scoring systems are well described and well validated. Scoring systems for bone erosions imaged by ultrasound have been described that either document the size and number of individual erosions or use a global score of the percentage of bone surface area affected by erosion. For ultrasound findings to be used as an outcome measure of bone erosion, studies of reproducibility and variability of such scores must be performed and the number of joints that need to be scored for erosion must be determined.

Osteophytes are also readily imaged using ultrasound, and recent imaging studies have noted the presence of both erosions and osteophytes in osteoarthritis of the hands.³⁰

Cartilage

Ultrasound can produce only limited views of cartilage in joints and was not originally considered useful for the diagnosis of cartilage disease, with MRI and arthroscopy being preferred. However, anatomic knowledge combined with optimal positioning of some joints (e.g., full flexion in the knee) can expose large areas of cartilage for direct examination, which is of diagnostic utility. Hyaline cartilage appears anechoic or hypoechoic and is located superficial to the hyperechoic bone cortex. Normal hyaline cartilage appears as a homogeneous, regular, hypoechoic layer, and the thickness of the cartilage can be measured at reference sites. Pathologic cartilage changes include the initial loss of regularity of the superficial surface, with the cartilage gradually thinning and initial focal cartilage defects becoming more generalized. It is not known if the more limited views of cartilage obtainable by ultrasound yield findings that correlate adequately with those obtained from the more extensive views provided by MRI and arthroscopy.

Fibrocartilage is more hyperechoic than hyaline cartilage but can also be visualized in sites such as the menisci of the knee and labrum of the hip and glenohumeral joints. Ultrasound can demonstrate inhomogeneity and irregularity of fibrocartilage and aid in the diagnosis of fibrocartilage tears

Fig. 42.8 Bone erosion in rheumatoid arthritis. Longitudinal view of second metacarpophalangeal joint shows generalized cortical irregularity in the metacarpal (MC) head with a large, well-demarcated cortical break (arrows) with associated hypoechoic synovial thickening and power Doppler signal within the erosion indicating synovitis. PP, proximal phalanx.

and cysts, although again MRI and arthroscopy can provide a more extensive view of the structures.

Soft tissue calcification and crystal-induced arthritis

Ultrasound is very sensitive for the detection of calcification in soft tissues because of the highly refractile nature of calcified tissues on ultrasound.³¹ Calcific deposits in calcific tendonitis of the shoulder can be diagnosed, localized, aspirated, and injected using ultrasound. Calcification within muscle hematoma or soft tissue calcification in connective tissue disease can also be readily identified. Calcification within hyaline and fibrocartilage occurs in chondrocalcinosis and calcium pyrophosphate crystal-induced arthritis. These calcifications can be identified within the cartilage substance on ultrasound. A common site is within the hyaline cartilage on the femoral condyle of the knee, where calcific deposits initially appear as hyperechoic intracartilaginous spots with subsequent formation of intracartilaginous linear deposits. Hyperechoic speckling can also be observed in the fibrocartilage of the menisci of the knee and calcific particles can be imaged within joint bursae or effusions.

Urate crystals aggregating in joints and soft tissues can be imaged as hyperechoic particles on ultrasound, although they are not usually as reflective as calcific deposits. Hyperechoic crystal aggregates can be observed within synovial fluid in acute gout, and tophi appear as circumscribed, heterogeneous, hyperechoic material in periarticular structures, tendons, and bursae. Ultrasound can be used to detect hyperechoic deposits of urate crystals lying on the surface of cartilage, which produce what is described as the “double contour” sign (Fig. 42.9, Video 42.5). Once a crystalline aggregate is detected, ultrasound has the additional advantage of being able to guide diagnostic aspiration.³²

Noninflammatory soft tissue disorders

Ultrasound provides better resolution of superficial soft tissue than does MRI. Because ultrasound involves real-time imaging, the operator can localize symptomatic structures in communication with the patient and perform dynamic assessments with either probe or finger pressure and movement to reproduce and localize painful symptoms. Therefore ultrasound is an excellent modality for examination of regional noninflammatory soft tissue disorders of peripheral joints and particularly those involving tendons and ligaments. These disorders are usually referred to as *tendinopathy* to differentiate the underlying noninflammatory cause, but the structural ultrasound features are often similar to those encountered in systemic inflammatory disease of tendons and ligaments. The most common sites of overuse tendinopathy encountered in rheumatology practice are the wrist (de Quervain tendonitis), elbow (epicondylitis), shoulder (rotator cuff tendonitis), hip (greater trochanter pain syndrome), knee (patellar tendinopathy), ankle (Achilles tendinopathy), and heel (plantar fasciitis).³³

The characteristic appearance of tendinopathy is hypoechoic enlargement of the tendon with widening of spaces between the tendon fibers due to increased ground substance. Neovascularization is observed as increased PD signal within the tendon, although histologic studies do not demonstrate an inflammatory infiltrate in the tissue as is observed in enthesitis or tenosynovitis of autoimmune inflammatory arthritis. Later stages of tendinopathy are characterized by partial or complete tendon rupture, which is characterized by hypoechoic loss of tendon substance. With complete tears there is also a lack of synchronous movements on dynamic scanning; this is also described as a *bell and clapper sign* in complete tears of both muscle and tendon.

Spine and sacroiliac joint

Ultrasound has a very limited role in spinal disease. MRI and CT are the optimal modalities for imaging of the sacroiliac joint, but one study has suggested that contrast-enhanced ultrasound may have a potential role in the diagnosis of sacroiliitis.³⁴ Ultrasound can also be used to guide spinal injection of the sacroiliac joints and pain medicine interventions in the spine such as rhizotomy.

Intervention

Ultrasound may be used to guide joint and soft tissue aspiration and therapeutic injection because the needle can be readily localized within musculoskeletal tissues as a hyperechoic reflective structure with typical acoustic reverberation artifact (Fig. 42.10, Box 42.1). Ultrasound-guided aspiration and injection are more accurate than injections using palpation guidance,

Fig. 42.9 Gout. (a) Acute gout of the first metatarsophalangeal (MTP) joint. Ultrasound shows acute inflammation with heterogeneous enlargement of the joint capsule and increased power Doppler signal due to tophaceous material and synovitis. (b) Double contour sign of gout is the appearance of a hyperechoic line superficial and parallel to the bone cortex caused by urate crystal deposition on the surface of cartilage. There are also focal hyperechoic speckles in the joint space caused by urate crystal aggregates. (c) Mixed hyperechoic and hypoechoic appearances of tophus adjacent to the first MTP joint. (d) Color Doppler ultrasound of tophus shows it to be hypervascular in this case of acute gout.

Fig. 42.10 Inflammation of the first metatarsophalangeal joint, presumed to be gout. (a) This patient had acute swelling of the big toe with pain and erythema. The diagnosis of gout was suspected, but the serum urate level was within normal limits. (b and c) These longitudinal images through the toe demonstrate a hypoechoic collection in the joint that was compressible and displaceable and consistent with an effusion. A needle (asterisks) was subsequently introduced into the joint under ultrasound guidance and withdrew a small amount of fluid. Analysis confirmed the presence of urate crystals. MT, metatarsal head; P, phalanx; SF, synovial fluid.

BOX 42.1 INDICATIONS FOR ULTRASOUND GUIDANCE OF INTERVENTION

1. Diagnostic fluid is required (ultrasound guidance improves success rate).
2. Palpation-guided injection has failed.
3. The target joint is deep lying (e.g., sacroiliac joint or hip).
4. The target joint is small (e.g., metacarpophalangeal, intercarpal joint).
5. The anatomy is distorted or difficult to ascertain due to deformity or obesity.
6. There are no bony landmarks (e.g., bursa or tendon sheath).
7. The target is adjacent to blood vessels or nerves (e.g., subtalar joint).
8. Injection of a nonsoluble substance (e.g., hyaluronic acid) is required.
9. Injection of a substance potentially toxic to nontarget soft tissues (e.g., radioactive synovectomy) is required.
10. A specialized procedure is necessary, such as synovial biopsy, muscle biopsy, soft tissue biopsy, nerve block, spinal facet joint injection, or rhizotomy.

and palpation-guided injections may be placed inaccurately in up to 50% of cases.³⁵ Ultrasound-guided injection has been regarded as a technically advanced skill, but a trainee was able to learn ultrasound-guided hip injection in a relatively short period with resultant high levels of accuracy.³⁶ In patients with inflammatory arthritis, a randomized controlled study confirmed that ultrasound guidance improved accuracy of corticosteroid joint injections but did not improve short-term outcome.³⁵ Other studies have noted that the application of ultrasound alters the site selected on clinical grounds to be injected and point out that this may be an important factor in improving outcome. Ultrasound-guided injection of the shoulder produced a better outcome than palpation-guided injection of the shoulder.³⁷ The techniques of ultrasound-guided injection are described more fully in Chapter 69.

NONMUSCULOSKELETAL TISSUE ULTRASOUND IN RHEUMATOLOGY

The application of ultrasound imaging in the rheumatology clinic for examination of musculoskeletal structures has been followed by its use to study a number of other nonmusculoskeletal conditions encountered in rheumatology.

Peripheral nerve

Peripheral nerves appear on ultrasound as hypoechoic structures bounded by a hyperechoic rim. For larger nerves the component nerve fibers can be visualized and have a similar appearance. Musculoskeletal ultrasound is ideal for assessing peripheral nerves, and most large and medium-sized peripheral nerves can be visualized with high-frequency ultrasound and a good anatomic knowledge of the nerve location. Ultrasound can be used both for diagnostic examination of peripheral nerves and for guidance of nerve block procedures.

The ultrasound features of the median nerve in carpal tunnel syndrome have been well described and have been correlated with the results of diagnostic electrophysiologic studies.³⁸ In entrapment neuropathy, the nerve develops a fusiform swelling thought to be caused by intraneural venous congestion and edema, and there may be increased Doppler signal within the nerve. The most consistent ultrasound diagnostic criterion in carpal tunnel syndrome is an enlarged cross-sectional area of the median nerve within the carpal tunnel, with a cutoff of more than 10 mm² being most commonly used. When small degrees of median nerve enlargement are assessed, it is important to confirm enlargement by evaluating the median nerve proximal to the carpal tunnel and to compare with the asymptomatic carpal tunnel. Causative pathologic processes such as anatomic anomalies, tenosynovitis, or a ganglion cyst can also be noted on ultrasound examination of the carpal tunnel. Nerve entrapment at other sites such as entrapment of the ulnar nerve in the cubital tunnel have also been described.

Vasculitis

Duplex ultrasound—gray-scale ultrasound and Doppler ultrasound—can readily visualize carotid, axillary, brachial, femoral, and temporal arteries, assessing both the lumen and the vessel wall.³⁹ Schmidt³⁹ described the temporal artery vessel wall inflammation and thickening in temporal arteritis as having a hypoechoic “halo” appearance in combination with luminal stenosis on ultrasound. These features on ultrasound have an overall sensitivity of 69% and a specificity of 82% compared with biopsy findings. Involvement of the proximal upper extremity arteries has also been described in large-vessel giant cell arteritis and Takayasu arteritis. Although very promising as a noninvasive first-line diagnostic technique, ultrasound has not replaced temporal artery biopsy in the diagnosis of temporal arteritis because of the absence of validated and standardized diagnostic criteria (Fig. 42.11, Video 42.6).

Fig. 42.11 Temporal arteritis and large-vessel giant cell arteritis. (a) Normal temporal artery following temporal artery biopsy. The artery lumen is patent with no stenosis and the vessel wall is hyperechoic and of normal thickness (confirmed on histologic analysis). (b) Temporal arteritis. The artery shows a narrowed lumen and thickened hypoechoic arterial wall. (c) Arteritis of the carotid artery. A skip lesion is seen on longitudinal view with hypoechoic arterial wall thickening. (d) Transverse view of the carotid artery showing the halo sign, a circumferential hypoechoic thickening of the arterial wall.

Parotid and salivary glands

Ultrasound can be used to assess the parotid, submandibular, and submental salivary glands and provides a noninvasive alternative to salivary gland biopsy in the diagnosis of Sjögren syndrome. Initially the salivary glands show diffuse enlargement with normal echogenicity; this gradually progresses to a heterogeneous ultrasound appearance with multiple round hypoechoic areas within the parenchyma. Increased PD signal may be observed in the glands. Advanced disease is characterized by large hypoechoic cystic change and atrophic changes in the residual gland tissue (Fig. 42.12). Ultrasound has been shown to have a good correlation with MRI and sialography in the diagnosis of Sjögren syndrome.⁴⁰

Skin

Because the skin is readily amenable to direct diagnostic inspection, the role of ultrasound is largely in the measurement of the thickness of skin involvement in psoriasis and scleroderma for purposes of disease monitoring. In psoriasis the plaque has both hyperechoic areas of hyperkeratosis and deeper hypoechoic subcutaneous skin inflammation, and this is associated with increased PD signal in the thickened hypoechoic tissue.⁴¹ Ultrasound measurement of dermal thickness in patients with systemic sclerosis has been described⁴² and allows differentiation of early hypoechoic edematous thickening and later hyperechoic fibrotic skin involvement. Ultrasound thickness of skin in scleroderma correlates with modified Rodman score.

CONCLUSION

Ultrasound imaging is now an integral part of clinical rheumatology practice because it provides immediate and objective diagnostic information and can be used to assist in a large number of interventional procedures. It has a developing role in the objective quantification of inflammatory musculoskeletal disease, but its application now extends beyond the joint to include many different tissues involved in rheumatologic disease (e.g., nerves, blood vessels, salivary glands). Future expansion of the use of ultrasound in rheumatology will require further standardization of diagnostic and quantitative

Fig. 42.12 Sjögren syndrome. Ultrasound image of swollen parotid gland shows hypoechoic change in the gland with almost complete loss of normal gland tissue and increased power Doppler signal in a patient with longstanding Sjögren syndrome.

techniques and international standardization and validation of ultrasound training.

Bone scintigraphy and positron emission tomography

■ CLIO RIBBENS ■ GAUTHIER NAMUR

- Bone scintigraphy with technetium-labeled diphosphonates is a nuclear medicine technique widely used for the investigation of bone and joint diseases. It is highly sensitive for depicting foci of increased bone turnover and increased blood flow, but uptake is nonspecific and combination with other imaging modalities, or the use of hybrid devices (SPECT/CT), is necessary for differential diagnosis.
- Positron emission tomography (PET) is a technique using molecules labeled with isotopes that emit positrons from their nucleus, the most widely used being 2-deoxy-2-[^{18}F]fluoro-D-deoxyglucose (^{18}F -FDG). ^{18}F -FDG accumulates in foci of increased glucose consumption, such as inflammatory lesions, which allows for direct identification of increased metabolic activity.
- PET devices are combined with computed tomography (PET/CT), which allows for precise localization and frequently even a morphologic description of the lesions with increased metabolic activity.
- The clinical applications of ^{18}F -FDG-PET include the detection of inflammation in various rheumatic diseases such as vasculitis, arthritis, lupus, or sarcoidosis, as well as the workup of fever of unknown origin.

INTRODUCTION

Imaging in rheumatology has greatly evolved in the past two decades, which has led to major advances in the clinical management of patients. Concurrently with the improvement in imaging techniques, with ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) being added to conventional radiography, nuclear medicine techniques have made progress not only in the research area but also in the clinical world. They play a role in both diagnosis and follow-up of inflammatory diseases.^{1,2} The most common nuclear medicine technique used in rheumatology is bone scintigraphy, but more recently developed methods such as positron emission tomography have emerged that provide information regarding the metabolic status of tissues in addition to the morphologic information provided by the other imaging modalities.

BONE SCINTIGRAPHY

Principles

The high affinity of diphosphonates for bone led to their use in imaging with technetium-99m ($^{99\text{m}}\text{Tc}$) labelling for bone scintigraphy in the early 1970s. The energy of the photon emitted by the $^{99\text{m}}\text{Tc}$ nuclide (140 keV) is well adapted to the physical properties of the current gamma cameras. On decay, radionuclides emit a gamma ray at their characteristic energies in different directions. Some of these rays interact with the gamma camera, whereas others may scatter, lose direction, or never interact with the camera.³ Gamma cameras acquire data in a single plane. The resultant images are therefore a two-dimensional representation of a three-dimensional subject, referred to as *planar imaging*. $^{99\text{m}}\text{Tc}$ -methylene diphosphonate (MDP) and $^{99\text{m}}\text{Tc}$ -hydroxymethylene diphosphonate (HMDP) are the most commonly used radionuclides for bone scintigraphy. Diphosphonates are either taken up by bone or rapidly cleared through the kidneys. Approximately 50% of the dose is distributed in the skeleton within 3 hours after

intravenous injection, with the remainder excreted in the urine.⁴ In a normally hydrated subject, less than 5% of the dose remains in the blood 3 hours after injection.⁴

Single-photon emission computed tomography

The disadvantage of planar images obtained with scintigraphy can be overcome by single-photon emission computed tomography (SPECT), which acquires volumetric data by rotating the gamma camera detectors around the patient. It offers images in three planes and has better spatial resolution. The main current clinical applications focus on evaluation of the skull and spine. The development of gamma cameras with tomographic capabilities combined with a CT scanner (SPECT/CT) introduced the concept of blended imaging devices providing complementary information, that is, a fusion image with functional (SPECT) and anatomic (CT) correlation. These cameras allow the simultaneous acquisition of tomographic scintigraphy and x-ray CT images. Scintigraphy is sensitive for the detection of active osteoarticular lesions but lacks specificity and does not provide anatomic landmarks. CT shows the anatomic details of osteoarticular structures perfectly and is able to highlight structural changes that are often quite specific of a particular disease or group of diseases. Unfortunately, these structural changes are the result of earlier phenomena of bone formation and osteolysis and provide few details about the active or inactive nature of a lesion. With SPECT/CT, the sensitivity of scintigraphy in detecting active lesions and the specificity of CT in revealing the nature of those lesions are associated. Moreover, the images from the two examinations are fused, which allows for precise localization of the otherwise poorly anatomically detailed scintigraphic abnormalities, which cannot be obtained with separate acquisitions (Fig. 43.1). The combination of the two techniques therefore leads to a real synergy.

Uses

Because the uptake of $^{99\text{m}}\text{Tc}$ -diphosphonates in bone depends on the osteoblastic activity as well as on the regional blood flow, bone scintigraphy is highly sensitive for many disorders causing increased bone turnover (Fig. 43.2). It lacks specificity, however, and distinguishing metastatic disease from osteoarthritis, for example, requires the use of other imaging modalities, or a SPECT/CT acquisition.

Bone scintigraphy is particularly useful when the arthritis is difficult to detect clinically, such as in sacroiliitis. Sacroiliitis may be detected on the basis of increased uptake of $^{99\text{m}}\text{Tc}$ -diphosphonates in the sacroiliac joints. A high uptake in these joints is also found in normal individuals,⁵ however, and the ratio of the peak sacroiliac joint count to the peak sacrum count is generally used, although normal values of this ratio can vary significantly depending on age and gender. Even so, the specificity is low, and other imaging modalities such as MRI are of better value for diagnosis of sacroiliitis in spondyloarthritis.⁶ Increased uptake of $^{99\text{m}}\text{Tc}$ -diphosphonates in arthritis, whether septic or not, is linked to increased blood flow, expanded blood pool volume, and vascular permeability, and the hyperemia involves not only the synovial membrane but also the juxtaarticular bones.⁷ This technique therefore cannot discriminate accurately between actively inflamed joints and chronically damaged joints⁸ and does not allow correct evaluation of inflammatory arthritis.

Use of other tracers

Given the limitations of $^{99\text{m}}\text{Tc}$, other radiotracers have been investigated for the evaluation of arthritis (Box 43.1). These radiotracers are not widely used, however, due to lack of specificity or concerns about the hazards associated with manipulation of labeled cells. Bone scintigraphy with

Fig. 43.1 Single-photon emission computed tomography (SPECT), computed tomography (CT), and SPECT/CT fusion images of right forefoot. (a) Maximal-intensity projection SPECT shows two foci of nonspecific disease located approximately in the right forefoot. (b) CT shows marginal erosions of several metatarsophalangeal and tarsometatarsal joints (first metatarsophalangeal is shown), as well as intraosseous para-articular lesions with soft tissue density compatible with tophi deposition. (c) Fusion SPECT/CT images clearly confirm the articular nature of the scintigraphic abnormalities and identify among the abnormal joints which ones are the site of active disease. A diagnosis of gouty arthritis is suggested.

Fig. 43.2 Right lateral, anterior, and posterior whole-body bone scintiscans in a patient with Paget disease showing involvement of the distal parts of both femurs, distal part of the left humerus, and right tibial diaphysis.

BOX 43.1 RADIOTRACERS INVESTIGATED FOR THE EVALUATION OF ARTHRITIS⁷

Gallium-67 (^{67}Ga) citrate
 Indium-111 (^{111}In) chloride
 Technetium-99m ($^{99\text{m}}\text{Tc}$) hexamethylpropylene amine oxime-labeled leukocytes
 $^{99\text{m}}\text{Tc}$ -labeled liposomes
 $^{99\text{m}}\text{Tc}$ -labeled polyclonal human immunoglobulin G monoclonal antibodies to granulocytes
 $^{99\text{m}}\text{Tc}$ -labeled anti-CD4 monoclonal antibodies

$^{99\text{m}}\text{Tc}$ -labeled diphosphonates therefore remains the standard nuclear medicine technique for assessing joint involvement in a whole-body approach.

POSITRON EMISSION TOMOGRAPHY

Background

In contrast to scintigraphy or SPECT in which molecules are tagged with radioisotopes emitting gamma rays, positron emission tomography (PET) uses molecules labeled with isotopes that emit positrons from their nuclei. These relatively short-lived positron-emitting isotopes are created in a cyclotron, a device used to accelerate charged particles, and include ^{15}O (half-life of 2 minutes), ^{13}N (10 minutes), ^{11}C (20 minutes), and ^{18}F (110 minutes). The most commonly used radiolabeled molecule, referred to as a *probe* or *tracer*, is 2-deoxy-2- ^{18}F fluoro-D-deoxyglucose (^{18}F -fluorodeoxyglucose or ^{18}F -FDG) in which one of the hydrogen atoms has been replaced by the ^{18}F radioisotope. ^{18}F -FDG is an analogue of glucose, and following intravenous

Fig. 43.3 Principles of positron emission tomography (PET). 2-Deoxy-2-[^{18}F] fluoro-D-deoxyglucose (^{18}F -fluorodeoxyglucose or ^{18}F -FDG) is a labeled glucose analogue in which the hydrogen atom in the 2 position is replaced by the ^{18}F radioisotope, a positron emitter. A positron is the antiparticle of an electron, with opposite charge. ^{18}F -FDG accumulates in cells proportionally to their glucose consumption. ^{18}F -FDG decays by emitting a positron from its nucleus. After traveling a short distance into the patient's body, this positron encounters an electron, which results in an annihilation process. This process involves the emission of two photons of 511 keV in diametrically opposite directions. These photons are registered by the PET "camera" as soon as they arrive at the detector ring. After the photon registration, the data are forwarded to a processing unit that decides if two registered events are selected as a so-called coincidence event. All coincidence events are forwarded to the image-processing unit where the final image data are produced via mathematical image reconstruction procedures.

injection it is taken up by cells according to their level of glucose metabolism. ^{18}F -FDG is transported through the cell membrane via glucose transporters into the cytosol and is phosphorylated by the enzyme hexokinase into ^{18}F -FDG-6-phosphate. In contrast to glucose, ^{18}F -FDG-6-phosphate cannot proceed further in the glycolytic pathway, and ^{18}F -FDG-6-phosphate is not further dephosphorylated and accumulates in the cell in proportion to the cell glucose consumption. ^{18}F decays by emitting a positron from its nucleus. This positron eventually collides with a nearby electron, which results in an annihilation event in which two 511-keV photons in the form of gamma rays are emitted approximately 180 degrees apart.³ These photons are detected by the PET "camera," a ring array of detectors (composed of scintillation crystals and photomultiplier tubes) around the patient. A single annihilation event results in the activation of detectors opposing one another, which is recorded as a "coincident event." Mathematical analysis of the coincident events yields the location of cell populations or tissues that have accumulated ^{18}F -FDG (Fig. 43.3). The spatial resolution of the most recent clinical PET scanners is approximately 4 to 6 mm.

Uses

The development of PET was closely linked to that of ^{18}F -FDG in the 1970s. PET was first used in cardiology and neurology, and the clinical application of PET was extended to oncology in view of the increased glucose metabolism in tumoral cells. The use of ^{18}F -FDG-PET for evaluating infection and inflammation arose from the occurrence of false-positive findings in patients undergoing evaluation for malignancy as well as from the demonstration of increased glucose metabolism in many inflammatory cell types and ^{18}F -FDG uptake by inflammatory tissues. Animal studies showed that ^{18}F -FDG uptake by tumors is due not only to the tumor cells themselves but also to the inflammatory cells (macrophages, neutrophils, fibroblasts, endothelial cells) appearing in association with growth or necrosis of the tumor.^{9,10} Therefore ^{18}F -FDG-PET is a fully tomographic technique, offering three-dimensional visualization of glucose metabolism. Compared with scintigraphy, it offers several advantages for the assessment of patients with inflammation. First, the ^{18}F -FDG uptake is directly related to the activity of metabolically active inflammatory cells, whereas bone scintigraphy detects the indirect hyperemia. Second, the spatial resolution and count rates of ^{18}F -FDG-PET are much improved compared with planar scintigraphy.¹¹ Finally, the uptake phase of ^{18}F -FDG is shorter than that of $^{99\text{m}}\text{Tc}$ -MDP, which allows a whole-body examination to be completed within an hour

and a half, whereas more than 4 hours (uptake plus acquisition) is needed for a bone scan. Furthermore, ^{18}F -FDG has a 110-minute half-life, which permits its use in centers distant from a cyclotron, and delivers a dose to the patient that is acceptable when compared with $^{99\text{m}}\text{Tc}$ -MDP.

Positron emission tomography/computed tomography

The advent of the combination of PET with CT in 2000 has allowed determination of the precise anatomic location (revealed by CT) of increased metabolic activity (provided by PET). The optimal methodology for performing and interpreting the PET/CT studies remains to be defined. To contribute fully to the diagnostic information, the CT scan should be acquired using the appropriate parameters in terms of beam collimation (which is related to slice thickness) and dose, possibly with the use of intravenous contrast agents. Whether such full diagnostic CT is really needed in addition to low-dose CT remains an unanswered question and probably depends on the justification for the examination. Still, there are no procedural guidelines for PET imaging of inflammation, whereas established procedural guidelines exist for tumor imaging with ^{18}F -FDG-PET^{12,13} that specify duration of patient fasting, activity of ^{18}F -FDG to be injected, and delay before image acquisition.

Finally, PET/MRI may become the blended-modality choice of the future,¹⁴ allowing for an even more precise anatomic localization of the increased metabolic activity with lower radiation exposure than PET/CT, which could be of particular relevance in pediatric patients. The development of targeted MRI contrast agents based on certain tissue metabolic properties leading to enhanced tissue contrast could further improve our knowledge of functional tissue properties and anatomic consequences of pathologic processes and hence of the cause and outcome of diseases.¹⁴

Applications of ^{18}F -fluorodeoxyglucose positron emission tomography in inflammatory diseases

PET can be used in the detection of inflammation in various rheumatic disorders with articular or extraarticular involvement, such as vasculitis, lupus, sarcoidosis, myositis, and arthritis, and can also be of help in the workup for fever of unknown origin.^{1,2}

Large-vessel vasculitis

The diagnosis of the large-vessel vasculitides giant cell arteritis and Takayasu arteritis relies on a spectrum of clinical, biologic, angiographic, and histopathologic features. It can be troublesome in some patients, and American College of Rheumatology criteria combining these various features have therefore been established. However, they do not have a specificity or sensitivity of 100% and were originally designed for classification and not diagnostic purposes. Histopathologic features cannot be obtained in Takayasu disease and can be missed in giant cell arteritis, in which biopsies should be performed bilaterally and in an extended manner. Imaging modalities such as Doppler ultrasonography, angiography and gadolinium-enhanced MRI can be useful in cases of suspected vasculitis but false-negative results can occur. Because glucose metabolism is increased in active vasculitis, ^{18}F -FDG-PET has been used in recent years in the evaluation of giant cell arteritis and Takayasu arteritis¹⁵⁻¹⁸ and could become a first-line investigative technique to allow a shorter and more successful diagnostic workup in the near future.¹⁷⁻¹⁹ Vascular uptake of ^{18}F -FDG is not specific for vasculitis and can also be found when atherosclerotic plaques are present. The two conditions can be differentiated, however, by taking into account the vascular distribution of the ^{18}F -FDG uptake pattern and the intensity of ^{18}F -FDG accumulation. A grading system has been developed by Meller and associates²⁰ and is based on comparison of the ^{18}F -FDG uptake by vessels and by the liver. Asymptomatic extracranial vessels can be affected in giant cell arteritis¹⁸ (Fig. 43.4). The common uptake pattern in great vessels in giant cell arteritis is linear and continuous and predominantly of grade II (i.e., vascular uptake similar to liver uptake); thoracic vessels are the most frequently affected, followed by abdominal vessels. ^{18}F -FDG-PET has been shown to identify significantly more affected regions than MRI. The whole-body evaluation procedure in ^{18}F -FDG-PET could therefore be of use in vascular screening and in identification of aortic uptake in these patients, who are known to develop aortic aneurysms more frequently. ^{18}F -FDG-PET can be used to evaluate the response to treatment (Fig. 43.5). However, it has not been shown to be useful for the prediction of relapses of giant cell arteritis.¹⁶ Furthermore, pathophysiologic features could be investigated because subclinical vasculitis has been highlighted by ^{18}F -FDG-PET in patients with polymyalgia rheumatica (Fig. 43.6), which is closely related to giant cell arteritis.

Fig. 43.4 ^{18}F -fluorodeoxyglucose positron emission tomographic images of a patient with giant cell arteritis. (a) The arrow in the coronal image points to an area of intense hypermetabolism of the abdominal aortic wall. (b) The arrowheads in the maximal-intensity projection image indicate hypermetabolism of the subclavian, axillary, and carotid arteries.

Fig. 43.5 Coronal ^{18}F -fluorodeoxyglucose positron emission tomographic images of a patient with vasculitis before (a) and after (b) treatment with corticosteroids. Note the disappearance of the aortic wall hypermetabolism on the posttherapeutic scan.

In Takayasu arteritis, the uptake pattern of ^{18}F -FDG is linear and continuous in the early phase (Fig. 43.7) but can become patchy in the late phase. In this disease, metabolic imaging with PET has been shown to be able to identify more vascular injured foci than does morphologic imaging with MRI. The latter, however, may provide information about changes in the wall structure or luminal blood flow. Hybrid PET/CT or PET/MRI imaging could therefore be of particular interest in large-vessel vasculitis.

Fig. 43.6 ^{18}F -fluorodeoxyglucose positron emission tomographic/computed tomographic fusion images of a patient referred for fever of unknown origin. Bilateral shoulder and hip hypermetabolism is highlighted, consistent with a diagnosis of polymyalgia rheumatica. Note the hypermetabolism of the subclavian arteries (arrows).

Fig. 43.7 Coronal ^{18}F -fluorodeoxyglucose positron emission tomographic image showing an intense hypermetabolism of the aortic arch and both subclavian arteries in a patient with Takayasu arteritis.

The combination of PET and CT has already been shown to be of value in Takayasu disease.²¹ The CT can increase the sensitivity of the PET modality in diseased vessels with weak ^{18}F -FDG uptake and can also help to localize accurately a mediastinal ^{18}F -FDG uptake coming from pulmonary arteries. On the other hand, ^{18}F -FDG accumulation can be found in arteries without vascular wall thickening on CT (i.e., areas of inflammation that have not yet progressed to vascular thickening).²¹ In summary, ^{18}F -FDG-PET is highly effective in evaluating in a single procedure the activity and extent of large-vessel vasculitis and may become a first-line imaging modality technique in patients suspected of having such vasculitis.

Systemic lupus erythematosus

^{18}F -FDG-PET is used in systemic lupus erythematosus (SLE) mainly to demonstrate central nervous system (CNS) involvement. Although MRI is the current gold standard for evaluating neuropsychiatric SLE, there are still problems with regard to sensitivity and specificity.²² The most common white matter hyperintensities can also be associated with hypertension and increase with age in the general population. Periventricular lesions associated with antiphospholipid syndrome can be impossible to differentiate from those of multiple sclerosis. Other neuroimaging techniques such as magnetic resonance spectroscopy, magnetization transfer imaging, SPECT, and PET have therefore been evaluated.²² PET can detect subtle brain changes in lupus patients. In a study of 22 lupus patients with severe or mild CNS symptoms, brain hypometabolism was detected by PET in all patients, most often affecting the parieto-occipital regions, whereas only half of the patients displayed abnormalities on MRI images.²³ The change in brain metabolism on follow-up PET scans correlated with the clinical outcome of cerebral symptoms.²³

Lymph node involvement can also be detected by PET in SLE,²⁴ as it can in amyloidosis secondary to SLE or to Sjögren syndrome²⁵ and in rheumatoid arthritis,²⁶ and must be differentiated from lymphoma. PET can also assess the distribution of activated lymphocytes and thus provide insight

into the pathophysiologic immune mechanisms of disease. Increased ^{18}F -FDG uptake has been found in the lymph nodes of patients with both active and inactive SLE, which suggests an enhanced metabolic and probably immunologic activity in lymphoid organs in SLE, even when the disease is clinically quiescent.²⁷ Furthermore, increased ^{18}F -FDG uptake was observed in the thymus of some SLE patients, even adults, but only in active SLE, which suggests a role for the thymus in SLE disease activity.²⁷

Sarcoidosis

The classical workup for patients with suspected sarcoidosis includes chest CT, which in patients with the disorder demonstrates bilateral hilar and mediastinal lymphadenopathy with or without lung parenchymal infiltrates or interstitial disease. However, the precise distribution of sarcoid disease cannot be determined by a single CT examination. Gallium-67 (^{67}Ga) scintigraphy has been widely used for the diagnosis of sarcoidosis, which shows the typical lambda sign attributable to mediastinal and hilar lymphadenopathy, as well as for management of the disease with detection of clinically silent sites and monitoring of therapeutic response.² PET can also provide a whole-body evaluation and detect unsuspected sites of involvement. It can reveal sarcoid lesions undetected by ^{67}Ga scintigraphy,²⁸ in particular in the abdomen. Both thoracic and extrathoracic sarcoid granulomas are detected with great sensitivity by PET/CT except for skin lesions, which can be identified visually.²⁹ Response to treatment can also be evaluated with PET.^{2,29} Thus ^{18}F -FDG-PET/CT is a valuable tool for the management of sarcoidosis, allowing for complete morphofunctional mapping of active inflammatory sites evaluation of treatment efficacy, especially in atypical, complex, and multisystemic forms of the disease²⁹ (Fig. 43.8).

Arthritis

The main application of ^{18}F -FDG-PET in arthritis concerns rheumatoid arthritis (RA). The first reports on the imaging of ^{18}F -FDG uptake in RA patients described incidental findings in patients undergoing PET for cancer screening or follow-up, who showed uptake in joints alone³⁰ or also in lung by rheumatoid nodules.³¹ The first specific studies involving rheumatoid joints go back to 1995, when Palmer and associates³² showed that PET could be used to quantify joint inflammation and that ^{18}F -FDG uptake in rheumatoid wrists was correlated with gadolinium uptake evaluated by MRI. Similarly, rheumatoid knees with ^{18}F -FDG uptake (Fig. 43.9) (i.e., PET-positive RA knees) exhibit higher ultrasonographically measured synovial thickness

and higher gadolinium-enhancement parameters on MRI than PET-negative knees.³³ Significant associations are found between the standardized ^{18}F -FDG uptake values (SUVs), which are correlated with ^{18}F -FDG tissue concentrations, and MRI parameters, synovial thickness measured by ultrasonography, serum level of C-reactive protein (CRP), and serum level of matrix metalloproteinase-3, a synovium-derived parameter reflecting joint inflammation.³³ These data clearly relate to animal studies showing that joint ^{18}F -FDG accumulation increases with the progression of arthritis and is correlated with the pannus rather than with the inflammatory cells around the joint; the main cell type responsible for FDG uptake is fibroblasts, and a dramatic increase in FDG uptake is induced by proinflammatory cytokines in fibroblasts and macrophages.³⁴ The main interest in the use of ^{18}F -FDG-PET in RA, however, grows out of the fact that it allows a whole-body evaluation of inflammation. Beckers and associates³⁵ studied RA synovitis in 21 patients with active RA and used the cumulative SUV (i.e., the sum of SUVs in PET-positive joints) as a measure of “metabolic” rheumatoid disease activity. This cumulative SUV was significantly correlated with clinical parameters (numbers of swollen and tender joints), biologic parameters (erythrocyte sedimentation rate and CRP levels), composite indices of disease activity (the 28-joint Disease Activity Score [DAS28] and Simplified Disease Activity Index), and ultrasonographic parameters (cumulative synovial thickness, number of Doppler-positive joints). Goerres and associates³⁶ also used ^{18}F -FDG-PET for global evaluation of RA, attempting to develop a simple score without using SUVs by adding the scores graded from 0 to 4 for each of the 28 joints included in the DAS28. The precise method for global evaluation of RA disease activity has not yet been standardized. The use of devices combining PET and CT will further improve the localization of metabolic activity and will be of great interest in evaluating small joints such as hands by making it possible to determine whether foci of increased activity are due to synovitis, inflammation of tendon sheaths (Fig. 43.10), or increased muscular uptake (Fig. 43.11b). Another potential future application of ^{18}F -FDG-PET could be the use of SUVs to

Fig. 43.8 ^{18}F -fluorodeoxyglucose positron emission tomographic image of a patient referred for fever of unknown origin associated with dyspnea and headache. (a) The coronal slice shows multiple intense hypermetabolic mediastinal and right hilar lymphadenopathies as well as a right pulmonary lesion (arrow). Transbronchial biopsy specimens showed nonnecrotizing granulomas. (b) The sagittal slice shows an unusual increased spinal cord uptake (arrows). The cerebrospinal fluid analysis highlighted a lymphocytic meningitis. The final diagnosis was pulmonary-mediastinal and neural sarcoidosis.

Fig. 43.9 (a) ^{18}F -fluorodeoxyglucose positron emission tomographic (^{18}F -FDG-PET), computed tomographic (CT), and fused PET/CT transverse sections of a normal knee. The CT helps to identify foci of relative hyperactivity seen on PET images posterior to the internal condyle and intercondylar notch (black arrows) as physiologic muscle uptake. (b) ^{18}F -FDG-PET, CT, and fused PET/CT transverse sections of the knee of a patient with rheumatoid arthritis. The PET (left) and fusion (right) images show a vast hypermetabolic ringlike lesion surrounding the condyles, consistent with a synovitis. Note the thickening of the synovium recognizable on the CT image (white arrow).

determine prognosis. In oncology, pretherapeutic SUVs have been shown to predict response to treatment and overall survival.^{37,38} The advent of effective but expensive biologic therapies in rheumatology has prompted an interest in methods that can detect changes in response to treatment with great sensitivity. The usefulness of PET in the assessment of therapeutic response has been shown for low-dose prednisone and methotrexate,³⁹ for intraarticular injections,⁴⁰ and recently for anti-tumor necrosis factor. In RA patients treated with anti-tumor necrosis factor, changes in ^{18}F -FDG uptake in knees were significantly correlated with changes in MRI parameters as well as with biologic parameters (CRP and matrix metalloproteinase-3 levels) after 4 weeks of treatment.³³ Global ^{18}F -FDG-PET joint score was decreased after three infusions of infliximab in patients showing a clinical response but not in those showing no clinical response.³⁶ Figure 43.11 illustrates the response to rituximab. Whether PET will be able to identify patients in need of biologic therapies or to detect an early response to these treatments remains to be shown.

^{18}F -FDG-PET can visualize joint inflammation in other inflammatory arthritides such as psoriatic arthritis⁴¹ and ankylosing spondylitis.⁴²

Accumulation of ^{18}F -FDG can also be found in various joints due to a local inflammatory reaction, even in degenerative disorders, such as bursitis or nonspecific synovitis in shoulder osteoarthritis (Fig. 43.12).⁴³ Uptake of ^{18}F -FDG by osteoarthritic joints has been found in shoulders,⁴³ hands,⁴⁴ and knees.⁴⁵ The favorability of the cost-benefit ratio of PET imaging in these diseases remains to be proven.

Fever of unknown origin

Many noninfectious inflammatory disorders treated by rheumatologists, such as arthritis and vasculitis (giant cell arteritis, Wegener granulomatosis, polyarteritis nodosa), can give rise to fever of unknown origin (see Figs. 43.6 and 43.8). Although ^{18}F -FDG-PET alone is sometimes unable to distinguish reliably between aseptic inflammatory disease and infectious disease or malignancy, it can localize active lesions and, in conjunction with other imaging modalities, identify the tissue or organ to be biopsied to establish a diagnosis.²

PRACTICAL ISSUES

As a rule, when ionizing radiation is being used in human studies, the level of exposure must be carefully taken into account. The effective dose resulting from a bone scan with $^{99\text{m}}\text{Tc}$ -labeled diphosphonates is 0.0057 mSv/MBq. The administered dose is typically 740 MBq, which gives an effective dose of approximately 4 mSv.⁴⁶ Doses in PET studies are within the same range (i.e., 5 mSv for 250 MBq of ^{18}F -FDG). The radiation exposure associated with the CT portion of a PET/CT study is highly dependent on the acquisition protocol. Low-dose studies such as those performed at the authors' institution and for which images are shown in Figures 43.7 and 43.9 through 43.12 result in an additional dose of 4.5 mSv.⁴⁷ Overall, the radiation burden may be considered minimal, and the theoretical risks are largely counterbalanced by the clinical benefits.

The cost of nuclear medicine techniques is linked to cost of the sophisticated machines themselves as well as to the cost of the isotopes used. The technetium-labeled isotopes used for scintigraphy are inexpensive, but their production is characterized by recurrent shortages. The isotopes used for PET are generated by a cyclotron, which needs to be within a few hours' reach of the user for practical purposes. Their cost can be highly variable but has tended to decrease due to greater availability.

Fig. 43.10 (a) ^{18}F -fluorodeoxyglucose positron emission tomographic (^{18}F -FDG-PET), computed tomographic (CT), and fused PET/CT coronal slices of the distal part of the right upper extremity in a patient with rheumatoid arthritis. (b) The PET (left) and fusion (right) images are strongly suggestive of inflammation of the ulnar bursa, in continuity with the flexor sheath of the fifth digit.

Fig. 43.11 ^{18}F -fluorodeoxyglucose positron emission tomographic (^{18}F -FDG-PET), computed tomographic (CT), and fused PET/CT coronal slices of the distal upper extremities in a patient with rheumatoid arthritis. (a) Inflammatory involvement of several proximal interphalangeal joints of both hands and multiple joints of both wrists. (b) Response to rituximab treatment. After 16 weeks, there is a complete metabolic response in the wrists and a partial response in the interphalangeal joints. Zones of relative hyperactivity in the left hand (arrow) correspond to physiologic muscle uptake.

Dual x-ray absorptiometry and measurement of bone

■ SYDNEY L. BONNICK

- Clinical guidelines for determining bone density are based on dual-energy x-ray absorptiometry (DXA) measurements of the posteroanterior lumbar spine and proximal end of the femur, with other skeletal sites and techniques being reduced to a lesser role.
- The World Health Organization (WHO) criteria remain the standard for diagnosing osteoporosis on the basis of bone mineral density (BMD).
- FRAX, the WHO's 10-year absolute fracture risk prediction algorithm, has refined prediction of the risk for fracture.
- Understanding precision and the least significant change is critical to interpretation of serial BMD measurements.
- New imaging applications for lateral spine DXA have extended the utility of DXA beyond the measurement of BMD.

INTRODUCTION

Dual-energy x-ray absorptiometry (DXA) was approved by the Food and Drug Administration (FDA) for clinical use in 1988. Because of its versatility and relative ease of use, DXA has become the dominant technology used to quantify bone density in clinical practice. Other technologies have had their utility diminish in the face of societal guidelines that rely on measures derived with DXA. Such guidelines also tend to focus on DXA measures of the posteroanterior (PA) lumbar spine and proximal femur, thereby diminishing the clinical utility of non-PA lumbar spine and proximal femoral sites.

The origins of bone densitometry can be traced to the field of dentistry in the late 1890s, but the birth of clinical densitometry did not occur until almost a century later with the approval of DXA for clinical use in 1988.¹ In DXA, photon energy is generated by an x-ray tube. Two distinct energy peaks are produced, either by filtering the photon energy or by pulsing the power to the x-ray tube. These two distinct peaks allow separation of bone from soft tissue. The magnitude of attenuation of photon energy through bone is compared with standards created from dried, defatted, ashed bone.

Initially viewed as a quantitative technique only, the current imaging capabilities of modern DXA devices have resulted in FDA approval for structural diagnosis in the spine and detection of abdominal aortic calcification. Bone mineral density (BMD) can be quantified in virtually every region of the skeleton, as well as in the skeleton as a whole. Analysis of body composition can also be accomplished with DXA and is considered by some to have replaced the previous "gold standard" of underwater weighing for this purpose. The primary applications of DXA, however, remain quantitative diagnosis of osteoporosis and prediction of fracture risk.

DIAGNOSIS OF OSTEOPOROSIS

Before the advent of quantitative definitions of osteoporosis based on measurement of bone density, osteoporosis was largely defined by the presence of a low-trauma fracture. In the late 1980s and early 1990s, a bone density that was 2 or more standard deviations (SD) below the young adult mean bone density had become the *de facto* working definition of osteoporosis. In 1994, the World Health Organization (WHO) redefined osteoporosis as a bone density that was 2.5 SD or greater below the young adult mean.² The WHO created other diagnostic categories based on measurement of bone density as well, as shown in Table 44.1. The threshold of 2.5 SD or greater below the young adult mean seemed reasonable because it created a prevalence of osteoporosis that was similar to previously observed lifetime risks for fracture. In creating four diagnostic categories, the WHO maintained the

recognized gradient of risk for fracture with declining bone density and the additional effect of prevalent fracture.

The original WHO criteria for diagnosis of osteoporosis based on measurement of bone density were described in terms of the number of standard deviations below the young adult mean bone density. Because this is the definition of the T-score used in bone densitometry, the WHO criteria are now generally characterized as T-score cut points, which are also shown in Table 44.1.

Although the WHO intended these criteria to be used for determining the prevalence of osteoporosis in world populations, they recognized the likelihood that the criteria would be applied to individuals as well. The WHO cautioned that different diagnoses could result depending on the skeletal site measured, the technique applied, and the reference database used. This was because the WHO criteria were derived from single-photon absorptiometry (SPA), dual-photon absorptiometry (DPA), and DXA bone density studies of the spine, proximal femur, and radius in white women.

A detailed discussion of controversies regarding the use of different methods for determination of bone density is presented in the online supplement.

Several authors have attempted to define T-score cut points for nonspine, non-proximal femoral measurements of bone density that would identify individuals with WHO-defined osteopenia or osteoporosis of the PA lumbar spine, proximal femur, or both.⁹ The results of such efforts identified T-score cut points that ranged from -1.9 to +1.06, depending on the site, technique, and objective of the cut point. It is thus clear that use of the WHO criteria at sites other than the spine or proximal femur and with techniques other than DXA can be inappropriate and misleading. This does not reflect a lack of accuracy or precision of measurements at these sites or with non-DXA devices. It simply reflects the effects of attempting to apply criteria developed by wholly different means. The unfortunate but predictable result of reliance on the WHO criteria for the diagnosis of osteoporosis is a dramatic reduction in the clinical utility of these non-DXA techniques and nonspine, non-proximal femoral skeletal sites. Although non-DXA technologies and nonspine, non-proximal femoral skeletal sites can be used for case finding for DXA studies of the spine and proximal femur, the bone density measured at such sites or with non-DXA devices should not be used as the sole determinant of the presence or absence of osteoporosis in the spine or proximal femur. The threshold for case finding also depends on the peripheral site and technology used for the initial measurement and should not be based on inappropriate application of the WHO criteria to bone density at the peripheral site.

The ISCD currently recommends that a gender-specific reference database be used when applying the WHO criteria to men older than 50 years. However, the IOF recommends the use of a white female reference database in conjunction with the WHO criteria for the diagnosis of osteoporosis in men.⁸ This recommendation stems largely from recognition that the difference in fracture rates between women and men is primarily due to non-bone density factors, not to differences in bone density. At a given level of bone density, the risk for fracture imparted by that level of bone density appears to be the same in both genders. Therefore, if the purpose of diagnosing osteoporosis based on some level of bone density is to imply a certain level of fracture risk imparted by that bone density, use of the white female reference database in men would be appropriate.¹⁰ This concept is gaining acceptance, although it is not the current standard in the United States.

PREDICTION OF FRACTURE RISK

Prediction of fracture risk with DXA bone density measurements is a separate entity from the diagnosis of osteoporosis. Although the four diagnostic

Even when the WHO criteria were applied to bone density measurements of the proximal femur in white women only, it became clear that there was enough variation in the proximal femoral reference databases between manufacturers to result in different diagnoses. This issue was addressed by Faulkner and colleagues,³ who demonstrated that substitution of a common proximal femoral reference database, the 1997 Third National Health and Nutrition Examination Survey (NHANES III) database, largely eliminated the differences in assignment of diagnostic categories. Since that time, the NHANES III proximal femoral database has become the standard proximal femoral database for white men and women. No other common reference database currently exists for any other skeletal site that could be used by manufacturers. Differences in assignment of diagnostic categories based on measurements of PA lumbar spine BMD among manufacturers are minimal, however, when compared with pre-NHANES III assessments of BMD at the proximal femur.

Applicability of the WHO criteria to men of any ethnicity and to non-white women is still controversial given that the original thresholds were chosen on the basis of reconciling fracture risk and prevalence established in white women. Similarly, because the original data came from DPA and DXA studies of the PA lumbar spine and proximal femur and from SPA studies of the radius, application of the WHO criteria to bone density studies at other skeletal sites with any technique or to the spine, proximal femur, and radius with other techniques remains controversial.

When other techniques and other skeletal sites are used, a given T-score may reflect only the variability in bone density in the population rather than

some level of fracture risk. In 1999, Faulkner and coworkers⁴ compared the T-score regression with age in women with the use of quantitative ultrasound (QUS) of the heel, quantitative computed tomography (QCT) of the spine, and DXA of the proximal femur, PA and lateral lumbar spine, and forearm based on the reference database provided by the manufacturer of the specific device. The expected T-score for an average 60-year-old woman ranged from -0.7 at the heel with QUS to -2.5 at the spine with QCT. In other words, the WHO diagnostic category could be normal to osteoporotic in the same woman, depending on the site and technique used. A study published in 2002 in men revealed similar findings.⁵ This dilemma resulted in part from different populations being used to create the reference databases for the various devices and skeletal sites, as well as from differences in the nature of the measurement with QUS, QCT, and DXA and in expected rates of bone loss in the various skeletal sites. It also reflected the effect of extending the WHO criteria beyond its original reach.

Findings such as these have led to recommendations from various organizations that use of the WHO criteria be restricted to specific skeletal sites measured with DXA. The International Society for Clinical Densitometry (ISCD) recommended that the WHO criteria be used only in conjunction with measurements of the PA lumbar spine, total hip, or femoral neck and that the lowest of the three be used.⁶ The WHO itself suggested that the criteria be applied only to measurements of the proximal femur with an emphasis on the femoral neck region of interest,⁷ whereas the International Osteoporosis Foundation (IOF) has stated a preference for the total hip region of interest.⁸

categories created by the WHO attempted to retain the concept of a gradient of increasing fracture risk with declining BMD, the four categories contain ranges of BMD that are too wide to use a category for accurately characterizing fracture risk in a given individual.

The ability to predict fracture risk with a single bone density measurement was considered controversial until 1993, when two published studies clearly demonstrated a statistically significant increase in the relative risk (RR) for fracture per SD decline in BMD for different types of fractures, as well as for specific fracture types when BMD was measured at different skeletal sites.^{11,12} RR was the appropriate statistical metric in these studies because it is the strongest indicator of the strength of the relationship between a risk factor, such as low bone density, and disease outcome, such as fracture. The utility of RR data in clinical practice is extremely limited, however, because its meaning is diminished when applied to the individual. Use of RR in clinical densitometry is no longer considered appropriate because there is now sufficient data to assess absolute risk. In 2008 the WHO introduced FRAX, a 10-year absolute fracture risk prediction algorithm for the prediction of risk for hip fracture and any major osteoporotic fractures, the latter including hip, clinical spine, humerus, and wrist fractures.¹³

FRAX is unique in predicting absolute fracture risk based on validated clinical risk factors, as well as BMD. Selection of the clinical risk factors included in the FRAX model was based on reviews of the medical literature to establish the magnitude of the relationship between the risk factor and fracture risk.¹⁴⁻²⁰ Ultimately, the data used to create FRAX came from 9 different study cohorts around the world and were validated in 11 other cohorts in similar geographic locations.²¹ The specific risk factors that were ultimately chosen came to be known as the WHO 8: age, body mass index, prior fracture, parental hip fracture, current smoking, glucocorticoid use, rheumatoid arthritis, and excessive alcohol consumption.

FRAX is available at no cost as an Internet-based application (www.shef.ac.uk/FRAX). A FRAX application for various devices and

desktop use is available for purchase. FRAX has also been incorporated into recent versions of DXA software. FRAX algorithms are available for different countries and, in some cases, for different ethnicities within a country. The FRAX data entry algorithm page from the website for U.S. white individuals is shown in Figure 44.1. The algorithm can provide an assessment of absolute fracture risk in the absence of BMD measurement; however, risk assessment is improved by inputting femoral neck BMD. The user should select the type of DXA machine from the drop-down box and then enter the femoral neck BMD. After clicking on “calculate,” 10-year absolute fracture risks are presented for hip fracture specifically and for any major osteoporotic fracture.

Clinical risk factors have been reduced to dichotomous variables requiring a “yes” or “no” response. The risk factor “prior fracture” refers to a low-trauma fracture occurring as an adult. The subjectivity of this assessment is unavoidable. Captured in this assessment are previous morphometric spine, clinical spine, nonspine, and hip fractures. The number, location, and type of preexisting fracture or fractures are not captured. If multiple fractures have occurred, the algorithm may underestimate the 10-year probability of fracture. When the risk factors are reduced to dichotomous variables, the inability to convey the effects of a “dose-response relationship” is inevitable. This limitation also applies to the risks associated with smoking, use of glucocorticoids, and alcohol consumption. Rheumatoid arthritis is considered separately from other causes of secondary osteoporosis because it imparts a risk for fracture that is independent of BMD.¹⁶ Therefore, if “yes” is selected for rheumatoid arthritis, this will contribute to calculation of the 10-year fracture probability regardless of whether a femoral neck BMD is entered. Selection of “yes” or “no” for other secondary causes of osteoporosis has no effect in this circumstance on the fracture probability calculation. If BMD is not entered and “no” is selected for rheumatoid arthritis and “yes” for other secondary causes of osteoporosis, the 10-year fracture probability calculation is affected by the selection of “yes” for other secondary causes of osteoporosis. If BMD is entered, there is no effect of the “yes” response to other secondary causes of osteoporosis on the 10-year fracture probability. When BMD is inputted, the contribution to fracture risk from secondary osteoporosis is captured in the BMD.

Some caveats are associated with the use of FRAX. First, the actual femoral neck BMD in g/cm² should be used rather than the T-score because the T-score used in FRAX calculations is based on the 1998 NHANES III proximal femoral database for white women, regardless of the gender or ethnicity of the patient. This should also be done even if the patient is a white woman because many DXA devices use the 1997 NHANES database rather than the 1998 database used by FRAX. When the BMD in g/cm² is entered, the FRAX program will calculate the requisite T-score from the 1998 NHANES III database.

The FRAX algorithm was never intended for use in patients receiving therapy. The algorithm does not account for the effect that pharmacologic therapy might have on reduction of fracture risk. It must then be assumed that FRAX risk predictions in individuals undergoing therapy will be overestimations of risk. Leslie and associates suggested that the 10-year major

TABLE 44.1
1994 World Health Organization criteria for diagnosis of osteoporosis based on measurement of bone density and T-score equivalent

Diagnostic category	Standard deviation (SD) below the young adult mean	T-score
Normal	≤1 SD	Equal to or better than -1
Osteopenia (low bone mass)	Between 1 and 2.5 SD	Between -1 and -2.5
Osteoporosis	≥2.5 SD	Equal to or poorer than -2.5
Severe (established) osteoporosis	≥2.5 SD + a fragility fracture	Equal to or poorer than -2.5 + a fragility fracture

The screenshot displays the FRAX WHO Fracture Risk Assessment Tool. The 'Calculation Tool' section is active, showing a questionnaire for a 69-year-old female with a weight of 60.69 kg and height of 166.88 cm. Clinical risk factors include previous fracture (No), parent fractured hip (No), current smoking (No), glucocorticoids (No), and rheumatoid arthritis (No). The femoral neck BMD is 0.761 g/cm², resulting in a T-score of -2.0. The 10-year probability of fracture is 21.3%. The results section shows a 17% probability for major osteoporotic fracture and a 3.3% probability for hip fracture. The tool also includes weight and height conversion options and a footer indicating it is for individuals assessed since June 1st, 2011.

Fig. 44.1 FRAX is a 10-year absolute fracture risk prediction algorithm developed by the World Health Organization that incorporates clinical risk factors for fracture and femoral neck bone mineral density (BMD). These data are for the patient whose bone density studies are presented in Figure 44.4a and b. (Image used with permission of the World Health Organization Collaborating Centre for Metabolic Bone Diseases, University of Sheffield, UK. FRAX is registered to Professor J. A. Kanis, University of Sheffield, UK.)

osteoporotic fracture risk might still be used in such individuals after retroactively calculating FRAX probabilities in more than 35,000 women older than 50 years from the Manitoba Bone Density Program and noting whether they had received pharmacologic intervention and their level of adherence.²² They found that only women highly adherent to at least 5 years of bisphosphonate therapy had an observed hip fracture risk lower than that predicted by FRAX. The FRAX major osteoporotic fracture risk was similar to the risk observed in all groups. This suggests that the FRAX 10-year major osteoporotic fracture risk can still be assessed in patients undergoing therapy but that the 10-year hip fracture risk may be overestimated in highly adherent patients after at least 5 years of bisphosphonate therapy.

Because of the inability to reflect a dose-response relationship for some of the clinical risk factors as noted previously, FRAX may also underestimate fracture risk in some circumstances. The ISCD and IOF jointly issued guidelines to address this problem in 2010.²³ These guidelines are available at www.iscd.org.

FRAX uses femoral neck BMD in its calculations. In circumstances in which the lumbar spine T-score is poorer than the femoral neck T-score, concern arose that FRAX would underestimate such a patient's fracture risk. Leslie and associates,²⁴ again using the Manitoba BMD database, suggested that the FRAX-calculated major osteoporotic fracture risk be rounded up or down as appropriate by 10% for each rounded T-score difference between the lumbar spine and femoral neck.

Importantly, FRAX does not indicate the necessity for treatment. Separate guidelines that incorporate FRAX risk predictions have been developed to help clinicians identify individuals who would benefit from pharmacologic interventions to reduce fracture risk.²⁵ Ultimately, FRAX should never substitute for clinical judgment in assessing fracture risk and the need for pharmacologic intervention.

Monitoring changes in bone density

Changes in bone density, whether attributable to disease or therapeutic intervention, can be quantified with DXA. Such changes cannot be interpreted properly without applying the concepts of precision and least significant change (LSC). Changes in bone density must also be measured at a clinically relevant skeletal site, with relevance being determined by the condition, disease, or drug that may cause the change in bone density.

In densitometry, precision refers to the ability to reproduce a quantitative measurement when the measurements have been performed under identical conditions in the setting of no real biologic change. When an individual has several bone density studies performed within minutes of each other, the results of each test are not expected to be identical because of variability in the measurement even when performed consistently perfectly, although the variability is expected to be small. Nevertheless, because there is variability, it must be quantified for the physician to know when the variability of the test has been sufficiently exceeded to conclude that a real biologic change has occurred. The variability of the test is its precision. Because variability is undesirable, this variability is also called the precision error of the test. Variability is most reasonably quantified by performing a short-term precision study.

To perform a short-term precision study, individuals undergo repeated bone density testing over a 7- to 14-day period, with studies on any one individual preferably not being performed on the same day.²⁶ The number of individuals and bone density studies per individual is based on narrowing the resulting confidence interval for the calculated precision value as much as reasonably possible. In general, the number of individuals and studies per individual is chosen to achieve 30 degrees of freedom.²⁷ Combinations such as 15 individuals studied three times each or 10 individuals studied four times each are often chosen to avoid learned positioning or excessive radiation exposure on the part of the subject undergoing many studies and the logistic issue of recruiting many subjects for the precision study. The individuals participating in the precision study should be representative of the patient population in which the resulting precision value will be applied.

Details on how precision is calculated are presented online.

IMAGING THE SPINE WITH DUAL-ENERGY X-RAY ABSORPTIOMETRY

Technologic improvements in image resolution with DXA have led to imaging applications for assessing vertebral deformities (vertebral fracture assessment [VFA]) and abdominal aortic calcification (AAC). With some DXA devices the spine can be imaged from T4 to L5 in seconds to minutes, depending on the scan mode, but always at a fraction of the radiation

exposure that occurs with conventional spine radiographs. Lateral spine DXA also largely avoids the problem created by parallax in plain radiography of the spine. Because movement of the scan arm allows the DXA beam to pass parallel to the vertebral endplates throughout the entire length of the spine, the vertebral dimensions are not distorted by the angle of the beam. If the patient has severe scoliosis, however, some parallax effect may be unavoidable.

Assessment for vertebral fractures

With VFA imaging, T4 to T6 may be poorly visualized. This does not generally present a problem because the majority of osteoporotic fractures occur below these levels. Assessment for previously undiagnosed vertebral fracture is imperative for accurate diagnosis, evaluation of fracture risk, and informed decision-making regarding the need for therapeutic intervention. The finding of a previously undiagnosed vertebral fracture may change the WHO diagnostic category and will change assessment of the patient's future fracture risk. Either or both may result in a different therapeutic decision. Studies in the medical literature have documented that the majority of morphometric vertebral fractures are undiagnosed. This seems to be true even in patients who have had radiographs taken in which the spine was visualized.^{29,30} Thus the ability to image the spine for diagnosis of vertebral fracture in conjunction with a bone density measurement is highly desirable in clinical practice. Of considerable importance is the finding that a significant percentage of women with nonosteoporotic bone densities have been found to have vertebral fractures. In a study by Schousboe and colleagues³¹ in which 342 women underwent lateral spine imaging with DXA, 27.4% of the patients 60 years and older with osteopenic bone densities according to the WHO criteria were found to have vertebral deformities consistent with a diagnosis of fracture. Forty-two percent of the patients 60 years and older with osteoporotic bone densities were found to have vertebral deformities as well. In 2007 the ISCD published extensive guidelines on patient selection for VFA.³² The guidelines assume that plain films of the spine have not previously been obtained and that knowledge of a vertebral fracture would change patient management. These guidelines are available at www.iscd.org. The ISCD also noted that the Genant visual semiquantitative method was the preferred method for VFA. In the Genant semiquantitative method the vertebrae are characterized as normal or deformed based on their appearance rather than their measured dimensions, as illustrated in the lower right-hand portion of Figure 44.2.³³ The VFA study in Figure 44.2 is from a 66-year-old man. No vertebral deformities are seen in this study. Because of the superb image resolution, small anterior osteophytes can be seen at T8. Some DXA VFA software now provides an automated Genant semiquantitative assessment of deformed vertebrae.

Assessment for abdominal aortic calcification

AAC can also be visualized during lateral spine imaging with DXA. Although several studies have suggested a relationship between aortic calcification and low bone density, a more important prognostic attribute of aortic calcification is its relationship to risk for myocardial infarction and stroke. A significant increase in the hazard ratio for myocardial infarction and in the RR for stroke with increasing aortic calcification was found in the Rotterdam study, a prospective population-based cohort study of almost 8000 men and women 55 years and older.^{34,35} The risk for congestive heart failure or coronary heart disease was also shown to be significantly related to the degree of aortic calcification in the Framingham Heart Study.^{36,37} Using the 24-point grading system for AAC seen on plain radiographs that was developed by Kauppila and coworkers,³⁸ an AAC-24 score of 5 or higher was associated with a significant increase in the risk for congestive heart failure or coronary artery disease.^{36,37}

Although the AAC-24 scoring system can be used with DXA VFA images, Schousboe and colleagues³⁹ proposed an 8-point grading system to improve its ease of use. The AAC-8 scoring system is shown in Table 44.2. Application of the AAC-8 scoring system to a VFA image is shown in Figure 44.3. Schousboe and colleagues⁴⁰ studied 174 postmenopausal women 55 years and older to compare performance of the AAC-24 and AAC-8 scoring systems on plain radiographs and lateral spine DXA imaging. The sensitivity of a lateral DXA AAC-8 score of 3 or higher for identification of women with an AAC-24 score of 5 or higher on plain radiographs was 62% with a specificity of 96%. The positive and negative predictive values associated with a lateral DXA AAC-8 score of 3 or higher were 82% and 89%, respectively. An AAC-24 score of 5 or higher on lateral DXA imaging had a sensitivity and specificity of 59% and 97%, respectively, for identification of women with an AAC-24 score of 5 or higher on plain radiographs. The positive and negative predictive values for a lateral DXA AAC-24 score of 5

Precision is calculated as the root-mean-square standard deviation (RMS-SD) rather than the arithmetic mean SD because use of the latter would result in underestimation of the gaussian error. RMS-SD is calculated by using the following equation:

$$SD_{RMS} = \frac{\sqrt{\sum_{j=1}^m (SD^2)}}{m} \quad (1)$$

where m is the number of patients in the precision study and SD is the SD for the scans on each patient. RMS-SD is expressed in units of measurement, which for DXA is g/cm². The RMS-SD precision value is used to calculate the LSC. LSC is the value that must be equaled or exceeded before a real biologic change can be said to have occurred.

The magnitude of the LSC is determined not only by the precision but also by the level of statistical confidence that is required and the number of measurements made at baseline and at follow-up. The formula for calculating LSC is shown in equation 2:

$$LSC = Z'(Pr) \sqrt{\frac{1}{n_1} + \frac{1}{n_2}} \quad (2)$$

where Z' (pronounced z-prime) is chosen from a z-distribution table found in many statistical texts based on the desired level of statistical confidence, Pr is the precision expressed as the RMS-SD, n_1 is the number of measurements performed at baseline, and n_2 is the number of measurements performed at follow-up. The ISCD recommends that the LSC be calculated at a 95% confidence level using a two-sided approach.²⁸ The Z' value for such a calculation is 1.96. Because common clinical practice is to perform one measurement at both baseline and follow-up, the value under the square root sign becomes 2. The formula for calculation of the LSC at a 95% confidence level with one measurement at baseline and one at follow-up then becomes

$$LSC = 1.96(Pr)1.414 = 2.77(Pr) \quad (3)$$

The LSC will also have the same units as those for precision.

Interpretation of the LSC is straightforward. If the LSC has been equaled or exceeded, a statistically significant change in BMD is said to have occurred, at whatever level of statistical confidence the LSC was calculated. If the LSC was not equaled or exceeded, no significant change in BMD is said to have occurred. When the LSC is calculated via a two-sided approach, as recommended by the ISCD, an increase or a decrease in BMD that equals or exceeds the LSC would be considered a significant increase or decrease. If the LSC is not known, serial measurements of bone density cannot be interpreted. It is simply not possible to know whether the variability in measurement has been sufficiently exceeded to conclude that a change has occurred in the patient.

The inherent precision of DXA is superb. Few, if any quantitative tests used in clinical medicine provide superior precision. Nevertheless, a short-term precision study must be done at the bone density facility to establish the precision of the test, from which the LSC can then be calculated. The precision at every skeletal region of interest that might be used to monitor bone density must be established. The same study population can be used for this, but precision must not be assumed to be the same at every skeletal site. Precision tends to be the best at the total hip and proximal forearm sites. The lumbar spine, trochanteric region, and femoral neck follow, generally in this order.

Better precision results in a smaller LSC. This generally means that less time is required between measurements to detect a statistically significant change in bone density. However, the anticipated rate of change in bone density at a particular site profoundly affects the time required to see a significant change. For example, precision is superb at the proximal forearm, but the rate of change at that site from commonly used bone-active agents is too slow for that site to have clinical utility in monitoring the effects of these agents on bone. In contrast, although precision at the lumbar spine or trochanteric region is not generally as good as that at the proximal forearm, the rate of change at these highly trabecular sites tends to be greater, thereby resulting in a shorter and more clinically useful interval to detect a statistically significant change in bone density.

Fig. 44.2 Lateral spine dual-energy x-ray absorptiometry (DXA) for assessment of vertebral fractures in a 66-year-old man. This study was performed with a GE Lunar Prodigy DXA device. No vertebral deformities are seen. The AAC-8 score is 0. Small osteophytes are visible anteriorly at the T8-T9 level. The Genant semiquantitative grading system is shown in the lower right portion of the image.

TABLE 44.2
AAC-8 scoring system

Abdominal aortic calcification (AAC) length relative to lumbar vertebral height	Score
None	0
1 vertebra	1
>1 but ≤2 vertebrae	2
>2 but ≤3 vertebrae	3
>3 vertebrae	4

A point score is awarded for the anterior abdominal aortic wall and the posterior abdominal aortic wall based on the number of vertebrae spanned by the length of the aortic calcification. The worst possible score for both walls combined is 8.

or higher on plain radiographs was 85% and 88%, respectively. Importantly, an AAC score of 0 on either the 8-point or the 24-point scale on lateral spine DXA images had a negative predictive value of 94% for an AAC-24 score of 5 or higher on plain lateral spine radiographs.

Identification of aortic calcification alone is not considered sufficient justification for performing lateral spine imaging with DXA. Nevertheless, the opportunity to assess this important risk factor for heart disease and stroke presents itself every time that VFA is performed.

APPLICATION OF BONE DENSITOMETRY IN CLINICAL PRACTICE

Different devices, different data?

Although the appearance of screen images and computer printouts from the various manufacturers of DXA equipment may vary, the information provided is actually similar. Figures 44.4 to 44.6 are screen images of PA lumbar spine and proximal femoral bone density studies from GE Lunar, Norland, and Hologic DXA devices. Careful review of the images will reveal that although the initial appearance is quite different among the three devices, the nature of the information provided is the same.

On the left of the GE Lunar DXA PA lumbar spine and left proximal femoral studies (shown in Figure 44.4), the skeletal images are depicted. On the lower right are the bone density results and standard score comparisons (T- and Z-scores) for various regions of interest. On the upper right is the age-regression graph. Above the graph is the notation that indicates from which region of interest the plotted data came. The colorful graph does not

Fig. 44.3 Lateral spine dual-energy x-ray absorptiometry performed for assessment for vertebral fractures in which abdominal aortic calcification is seen. The AAC-8 score was 6. (Case provided courtesy Hologic, Inc., Bedford, Mass.)

provide any additional information beyond the numbers seen on the lower right. On the bottom portion of the screen, relevant biographic data are presented. On the Norland PA lumbar spine and left proximal femoral DXA studies seen in Figure 44.5, the layout is similar but not identical. An obvious difference is that images of the spine and proximal femur are in color, although they can be changed to gray-scale images if desired. The age-regression graph is seen on the upper right of the image and numerical data across the bottom of the image.

Fig. 44.4 (a) Posteroanterior lumbar spine study performed with a GE Lunar Prodigy DXA device on a 69-year-old woman. Bone mineral density (BMD) and standard scores are given for each vertebra, as well as for every possible combination of contiguous vertebrae. L1-L4 BMD is plotted on the age-regression graph. (b) Left proximal femoral study performed with a GE Lunar Prodigy device on the same patient.

Figure 44.6 shows PA lumbar spine and left proximal femoral studies obtained with a Hologic DXA device. The age-regression graph is not seen on this particular screen image; however, it is provided on the computer printout. Patient biographic data are clearly seen on the upper right, and once again, numerical data are provided on the lower right.

In the GE Lunar spine study in Figure 44.4a, a BMD value is given for each of the four lumbar vertebrae and for every possible combination of contiguous lumbar vertebrae. This is not the case with the Norland DXA spine study seen in Figure 44.5a. Note that in the Hologic PA spine study in Figure 44.6a, L1-L4 BMD is referred to as the “total” rather than L1-L4, as it is in the GE Lunar and Norland studies. In the proximal femoral studies shown here, all the manufacturers provide results for the total hip, femoral neck, and trochanteric regions of interest. In the GE Lunar and Norland but not the Hologic proximal femoral studies, values are provided for Ward’s area. This difference is of little consequence because Ward’s area, though of historical interest, has little, if any, clinical utility in the individual.

The age-regression graphs are simply plots of BMD from the selected region of interest versus the patient’s age. The center regression line

indicates the expected BMD for age. The upper and lower boundaries of the center regression line are ± 1 SD or ± 2 SD, depending on the manufacturer. This is a visual representation of the comparison to the patient’s age and gender-matched peers. The numerical comparison is found in the standard scores. In the case of the Norland graph, the background color scheme of green, yellow, and red also corresponds to the WHO T-score diagnostic category cut points. Fracture risk characterizations are made within these different colored zones. Note, however, that these colored zones span the entire age range shown on the graph and thus must be interpreted with extreme caution.

All the manufacturers provide standard score comparisons for BMDs from the various regions of interest. The standard score comparisons indicate the number of standard deviations above or below the average value in which the patient’s value lies. The T-score is a comparison to the average for a young adult and the Z-score is a comparison to the average for the patient’s age-matched peers. The T-score is used with the WHO diagnostic criteria as shown in Table 44.1. A Z-score poorer than -2 suggests the need to evaluate a patient for secondary causes of bone loss. However, a Z-score

Fig. 44.5 (a) Posteroanterior lumbar spine study performed with a Norland DXA device. (b) Left proximal femoral study on the same patient. Note the density-modulated color images of the skeleton. The chosen region of interest is plotted on the age-regression graph. The boundaries of the graph are twice as wide as those seen on the GE Lunar studies. (Case provided courtesy Cooper-Surgical Norland, Trumbull, Conn.)

of -2 or better does not negate this possibility, and evaluation for secondary causes of bone loss should always be considered in an individual with low bone density.

The image of the skeleton should be reviewed to confirm proper patient positioning, correct labeling of the regions of interest, and identification of any potential artifacts or structural changes that would affect the accuracy of the bone density measurement. It may be necessary to review the image on the computer itself rather than the printout because resolution of the image will be superior on the computer screen. Unlike VFA images, bone density images have not been approved by the FDA for structural diagnosis, but the nearly radiographic quality of these images makes such a structural review appropriate. Once the image has been reviewed and the physician is satisfied with the technical quality of the study, only then should the all-important numerical data be addressed.

On the PA lumbar spine study, the L2-L4 or L1-L4 BMD value is preferred over BMD values from a single vertebra or from only two contiguous vertebrae. This preference is for reasons of accuracy and precision. All major manufacturers of DXA equipment provide the L1-L4 BMD, although as noted earlier, on Hologic studies this is called the "total." At the proximal femur Ward's area is the least accurate of all the proximal femoral measures as a result of its very small size. Because of the localization routines used

in these devices, Ward's area should be expected to have the lowest BMD. Ward's area is also placed slightly differently from manufacturer to manufacturer. This is true for the femoral neck as well. The most similar region of interest among the manufacturers in the proximal femur is the total femoral region of interest. Even so, the actual measured BMD at a given skeletal site should never be directly compared among the manufacturers because of differences in machine calibration. At the proximal femur, a rough comparison of total hip T-scores can be attempted only if the T-scores are derived from the same NHANES III database.

A CASE STUDY

A 69-year-old postmenopausal white woman was referred for a DXA PA lumbar spine and proximal femoral study after a wrist fracture, which she suffered in a fall from a standing height on a wet surface. Her baseline studies are the GE Lunar studies previously seen in Figure 44.4. A review of the spine image indicated good positioning and no apparent degenerative changes, artifacts, or vertebral deformities that would affect the accuracy of the study. The vertebral labeling also appeared to be correct. A review of the left proximal femoral study also indicated good positioning and no artifacts

Fig. 44.6 (a) Posteroanterior lumbar spine study performed with a Hologic DXA device. Note that L1-L4 bone mineral density (BMD) is called the total BMD. BMD values and standard scores are provided for each vertebra as well. (b) Left proximal femoral study on the same patient. (Case provided courtesy Hologic, Inc., Bedford, Mass.)

that would affect the accuracy of the study. Applying the WHO criteria for diagnosis and the ISCD guidelines for application of the WHO criteria, the L1-L4 T-score of -2.2 should be used for diagnosis. Thus this patient has osteopenia. Her 10-year absolute risks for hip fracture and major osteoporotic fracture calculated with FRAX are shown in Figure 44.1. The NOF recommends consideration of pharmacologic intervention in postmenopausal women with osteopenia and a FRAX 10-year absolute hip fracture risk of 3% or greater or a 10-year major osteoporotic fracture risk of 20% or greater.²⁵ Applying these guidelines, treatment with an antiresorptive agent was subsequently begun.

To assess therapeutic efficacy, the patient underwent bone density testing after 2 years of therapy. Her BMD at this time was 0.971 g/cm^2 at L1-L4, 0.797 g/cm^2 at the femoral neck, and 0.796 g/cm^2 at the total hip site. BMD in the three regions appeared to have increased. Before the physician can conclude that this has indeed happened, several things must be considered.

First, was the same type of machine used for both the baseline and follow-up studies? The answer here is yes. Not only was the same type of machine used, but exactly the same machine was used. This is extremely important. If a different manufacturer's machine had been used between

baseline and follow-up, the BMD values could not be compared. When two different machines from the same manufacturer are used, a comparison can be made but the LSC cannot be calculated directly and must be assumed to be greater than it would otherwise be. In addition to the same machine being used, the same technologist performed both sets of studies, which was the best possible circumstance. Next, it is important to ensure that adequate quality control monitoring of the machine was performed during the period in question. The bone densitometry facility must perform quality control procedures at least as often as recommended by the manufacturer and track the results. Drifts and shifts in machine values can and do occur. If they are not recognized and corrected, comparisons of values even on the same machine are not valid. Another area of concern is any software changes in the interim that could potentially affect the values. If the software version is the same between the two scans, this concern is moot. Finally, were comparable regions of interest identified on the two sets of scans? In other words, is an "apples to apples" comparison being made? The images from both sets of studies should be compared to determine that similar regions of interest were identified and labeled. Once all these preliminary issues have been resolved, the final issue to undertake is to determine whether the change measured equals or exceeds the LSC. This means, of course, that

TABLE 44.3

A comparison of current guidelines from major medical organizations for the use of bone density testing in clinical practice

	Women ≥65 yr	Postmenopausal women ≤64 yr and at least 1 risk factor	Postmenopausal women with fractures	Men ≥70 yr	Technique for diagnosis	Site for diagnosis
NOF 2010	✓	✓	✓	✓	DXA	PA lumbar spine, total hip, or femoral neck, whichever is lowest
AACE 2010	✓	✓	✓*	—	DXA	Spine, proximal femur, proximal radius
NAMS 2010	✓	✓	✓	—	DXA	PA lumbar spine, total hip, or femoral neck, whichever is lowest
ISCD 2007	✓	✓	✓	✓	DXA	PA lumbar spine, total hip, or femoral neck, whichever is lowest

*Consideration was limited to low-trauma fractures.

precision of testing at a given skeletal site must previously have been determined.

In this case, calculations from an earlier short-term precision study indicated that the RMS-SD was 0.012 g/cm² at L1-L4, 0.006 g/cm² at the total hip, and 0.011 g/cm² at the femoral neck. To calculate the LSC, as recommended by the ISCD, each of these values was multiplied by 2.77. The resulting LSCs were 0.033 g/cm² at L1-L4, 0.017 g/cm² at the total hip, and 0.031 g/cm² at the femoral neck. The changes measured at L1-L4, the total hip, and the femoral neck all exceed their respective LSCs. Based on these comparisons, it is appropriate to conclude that a statistically significant increase in BMD occurred in all three regions of interest and that based on the intermediate endpoint of BMD, the antiresorptive therapy was efficacious. If the changes measured in BMD had not equaled or exceeded the LSC at any region of interest, the appropriate conclusion would have been that no change in BMD had occurred at that region. No change in BMD would also suggest therapeutic efficacy. If, however, a decline in BMD had been observed that equaled or exceeded the LSC, a statistically significant loss of BMD can be said to have occurred, a circumstance that should prompt reevaluation of the patient.

LIMITATIONS OF BONE DENSITY TESTING WITH DUAL-ENERGY X-RAY ABSORPTIOMETRY

The limitations of DXA bone density testing should not detract from the extraordinary clinical utility of the technology. DXA is a two-dimensional measurement. As a consequence, measurements of bone density are mixed measurements of trabecular and cortical bone, unlike three-dimensional QCT, in which the trabecular and cortical components can be separated. Because DXA is an x-ray-based technology, exposure to ionizing radiation is unavoidable. However, radiation exposure is extremely low and, from a practical clinical perspective, virtually negligible. The accuracy and precision of bone density measurements can unquestionably be affected by degenerative skeletal changes, which are common in the spine after 60 years of age. Thus, less reliance should be placed on PA lumbar spine BMD in individuals of this age and greater reliance placed on proximal femoral measurements. Surgical hardware or previous fractures will also render a measurement invalid at the site of the hardware or fracture.

Perhaps the most controversial limitation of DXA, which also applies to measurement of bone density with any other technique, is the recognition that measurement of bone density does not capture every determinant of fracture risk and, conversely, measurement of bone density does not capture every aspect of the therapeutic efficacy of bone-active agents in reducing fracture risk. Nevertheless, there is unquestionably a statistically significant and exponential relationship between declining BMD and increasing fracture risk. A single measurement of BMD is predictive of future fracture.^{11,12} Absolute fracture risk prediction algorithms such as FRAX go beyond the recognized limitations of measurement of BMD to refine the fracture risk prediction. BMD is considered an intermediate endpoint in assessing the therapeutic efficacy of a bone-active agent in reducing fracture risk. Because no agent reduces the risk to 0, the presence or absence of a fracture while receiving therapy cannot be used as a measure of efficacy. There is a statistically significant relationship between increases in BMD with therapy versus placebo and decreases in fracture risk.⁴¹⁻⁴³ It is only the magnitude of this relationship that remains controversial.⁴⁴ At present there is no better quantifiable measure of therapeutic efficacy than a measurement of BMD indicating stability or an increase in BMD.

INDICATIONS FOR BONE DENSITY TESTING

Several organizations have published thoughtful guidelines on patient selection for bone density testing. In general, most guidelines reflect the positions taken by the NOF, which issued its first guidelines for physicians on the use of bone densitometry in 1988. The NOF's most recent guidelines were issued in 2010.²³ Other organizations such as the ISCD, the American Association of Clinical Endocrinologists (AACE), the North American Menopause Society (NAMS), and the American College of Rheumatology (ACR) have issued guidelines as well.⁴⁵⁻⁴⁸ Guidelines from the AACE⁴⁶ and NAMS⁴⁷ are provided in the context of prevention and treatment of postmenopausal osteoporosis and are therefore understandably focused on postmenopausal women only, whereas guidelines from the NOF,²³ ISCD,⁴⁵ and ACR⁴⁸ address bone density testing in both men and women. In all the guidelines, however, bone density testing is recommended for women 65 years and older regardless of other risk factors. In guidelines from the NOF, ACR, and ISCD, bone density testing is recommended in men 70 years and older. A comparison of the guidelines is presented in Table 44.3.

Various organizations have also provided guidelines on the frequency of testing when monitoring changes in bone density. Most organizations do not recommend the use of an appendicular skeletal site for this purpose. Instead, bone density measurements at the lumbar spine or proximal femur are preferred. In its 2010 recommendations, the ACR advised that patients initiating glucocorticoid therapy at any dose with a planned duration of 3 or more months undergo baseline bone density testing. Serial measurements as part of monitoring were also suggested, but the ACR noted that the appropriate interval remains controversial.⁴⁹ If the patient was receiving therapy to prevent glucocorticoid-induced bone loss, annual follow-up measurements were recommended. The ISCD, though noting that 1 year after initiation or change in therapy was an appropriate monitoring interval, also stated that in conditions associated with rapid bone loss such as glucocorticoid therapy, more frequent testing was appropriate.⁴⁵ Both the AACE and NAMS, which focused on postmenopausal osteoporosis, provided different recommendations based on the treatment or bone density status of the woman. NAMS recommended a monitoring interval of 2 to 5 years in untreated women and a monitoring interval of 1 to 2 years in women receiving treatment.⁴⁷ AACE recommended a monitoring interval spanning 1 to 10 years in untreated postmenopausal women, depending on their initial BMD and anticipated rate of loss.⁴⁶ In women being treated for osteoporosis, measurements were recommended every 1 to 2 years until stability was demonstrated. Thereafter, a monitoring interval of 2 years was recommended but could be lengthened with demonstration of persistent stability. The guiding principle behind all these recommendations is reflected in the ISCD guidelines,⁴⁵ in which it is noted that "follow-up BMD testing should be done when the expected change in BMD equals or exceeds the LSC."

CONCLUSION

Clinical guidelines are based on DXA measurements of the PA lumbar spine and proximal femur, with other skeletal sites and techniques being reducing to a lesser role. The WHO criteria remain the standard for diagnosing osteoporosis based on BMD. The WHO's 10-year absolute fracture risk prediction algorithm FRAX has refined fracture risk prediction. Understanding precision and the LSC is critical to the interpretation of serial bone density measurements. Finally, new applications for DXA lateral spine imaging have extended the utility of DXA beyond the measurement of BMD to identification of spinal fractures and assessment of aortic calcification.

Use of imaging as an outcome measure in rheumatoid arthritis, psoriatic arthritis, and ankylosing spondylitis in clinical trials

■ DÉSIRÉE VAN DER HEIJDE

- The general methodology used for scoring and analyzing the results should be applied to imaging as part of clinical trials.
- In rheumatoid arthritis, radiographs of the hands and feet are the preferred imaging method for assessing structural damage in clinical trials.
- Magnetic resonance imaging (MRI) may be useful in early drug development for rheumatoid arthritis and psoriatic arthritis.
- In ankylosing spondylitis, MRI of the sacroiliac joints and spine gives important information on inflammation, whereas radiographs are still the standard for assessing structural damage.

INTRODUCTION

Imaging is an important way to assess the efficacy of treatment in clinical trials. Depending on the imaging technique, it can be used to assess inflammation, structural damage, or both. The focus of this chapter is predominantly on structural damage. It is this aspect that makes imaging an important outcome measure in clinical trials. To show that a drug has the capability of modifying disease, a reduction in the signs and symptoms (of inflammation), preservation of physical function, and inhibition of progression of structural damage must be demonstrated. Some general concepts about using imaging as an outcome measure are discussed first. Because assessment of structural damage on radiographs is well established for rheumatoid arthritis (RA), it will frequently be used to illustrate the concepts. This is followed by a discussion of specific issues by disease for RA, psoriatic arthritis (PsA), and ankylosing spondylitis (AS) and by imaging method (conventional radiography, magnetic resonance imaging [MRI], and ultrasonography).

GENERAL ASPECTS FOR CLINICAL TRIALS

With respect to clinical trials, some general aspects apply to all imaging methods and scoring in general, as well as handling of the data. These aspects are summarized as points to consider and include the following:

- Different phases of drug development
- Different phases of disease
- Readers
- Statistical aspects of reader agreement
- Grouping of films—reading sessions
- Blinding time sequence
- Statistical handling of missing data
- Statistical analyses
- Minimum duration of trials
- Placebo versus active comparator
- Presentation of data
- Repair

Different phases of drug development

The choice of imaging method depends on what feature will be assessed (inflammation vs. damage), duration of follow-up, and experience with various imaging techniques in centers, including patients. In the early phases of development the most important issue is proof of concept. This might apply to imaging of inflammation and structural damage. For the first, only MRI and ultrasonography are applicable; for damage, radiographs can also be used. MRI is more widely standardized and applied than ultrasonography in clinical drug development. Information on bone damage (edema and erosions) in RA can be obtained with MRI, whereas radiographs provide insight on the effect on bone (erosions) and indirectly on cartilage (joint space narrowing [JSN]). In later phases of drug development the data will be used for filing to drug agencies. At the moment radiographs are used for this purpose. Acceptance of MRI needs to be discussed at the outset.

Different phases of disease

In principle, the same imaging techniques can be used with early and advanced disease. Progression of structural damage on radiographs is most prominent in patients who already have structural damage. On theoretic grounds it might be especially useful to apply MRI in the early phases of the disease before structural damage can be visualized on radiographs.

Readers

Because precision of reading is important, it is advised that two readers score all the images independently. The average data from the two readers will then be used for the primary analysis. Ideally, these same two readers score all images, but if not possible, three or four readers can score the images so that a set of two scores is available for each film. Preferably, the readers score a similar number of images and all possible reader combinations are made. Which reader should read which image should already be decided before commencement of the reading. Increasing the number of readers to three or more for all images would further improve the precision but at the cost of feasibility (including time and cost).¹ For pivotal clinical trials the optimal number of readers is two; however, for observational studies or early-phase development scores, one reader could be sufficient. It is also important to use experienced, well-trained readers because the consequent reduction in random error increases the power of a study over the use of untrained readers.

Statistical aspects of reader agreement

An important aspect is assessment of the agreement of the readers. Traditionally, this is done with the intraclass correlation coefficient (ICC), which can be defined as the proportion of all the variance explained by differences between subjects, that is, suggesting a small contribution from observer variation. The Pearson and Spearman correlation coefficients should be avoided because they give only a measure of association, not agreement. Nevertheless, the ICC also clearly has limitations because it is largely influenced by the data set: a data set with great variation in the data yields higher ICCs than does a data set with minor variation, although this is not a reflection of better agreement between the readers. This issue is especially

Fig. 45.1 The Bland and Altman plot can be applied to status scores and to change scores. On the x-axis the mean score of the two readers is depicted and plotted against the difference between the scores of reader 1 and reader 2 on the y-axis. If no variation is present, all data will be on the line $x = 0$ (which indicates that the difference between the readers is 0 for all values). If the mean difference is not equal to 0, one of the readers is systematically scoring higher than the other reader. It is important to check whether the variation between the readers is equal over the entire range of the scores. The limits of agreement do include 95% of the data, and this is a value for the random variation (the gray zone in the figure). This forms the basis for calculation of the smallest detectable difference and smallest detectable change.

pertinent when comparing the agreement of progression scores, which are typically small. Consequently, the ICC might suggest poor agreement whereas it is actually caused by lack of variation in the data. An additional analysis for checking agreement between readers is use of the Bland and Altman plots (in which the difference between the two readers is plotted against their mean), which assess real agreement in the units of the measurement scale.² An example is presented in Figure 45.1. Calculating the 95% limits of agreement provides a value that is also referred to as the smallest detectable difference (SDD), which can be used as a cutoff to determine whether a change beyond measurement error is present. The SDD reflects the situation for testing whether a change in patient A is different from a change in patient B. Mostly, we are interested in the question whether a change in patient A is a real change, in other words, whether there is a change beyond measurement error in this particular patient. For this purpose the smallest detectable change (SDC) should be used,³ which can be derived from the SDD by dividing by the square root of 2. The disadvantage of both the SDD and SDC is that they are frequently relatively high numbers and underestimate real progression because progression judged by clinicians as being clinically relevant (e.g., sufficient to change treatment) is usually below the SDD or SDC. So the best value of SDD and SDC lies in obtaining information for judging the level of agreement of reader pairs, but if used as a cutoff to determine progression, it will most likely underestimate the number of patients with progression.

Grouping of films—reading sessions

Typically, all the images from different time points that will be analyzed together are scored in the same reading session and are offered simultaneously to the reader. For example, a 1-year trial with images at weeks 0, 24, and 52 is offered at the same time to the reader. Although most scoring methods provide absolute scores, the option to compare images at various time points is an important aspect of scoring; in addition, by doing so, differences in imaging technique (e.g., overexposure or underexposure, rotation) can be taken into account. Moreover, change scores are the most important for analysis of treatment effect. A consequence of this is that if for the trial in the example the week 104 film becomes available, rescoring of the earlier time points is required. A rule is that all the data that will be used in one analysis or comparison need to be included in the same reading. It is of major importance to define at the outset which time periods need to be compared to select the correct images for follow-up reading sessions. Especially in the current trial environment with minor progression in many patients, the optimal reading circumstances are of major importance.

Blinding time sequence

The advantage of images is that they can easily be blinded for patient identity and treatment group and rescored at later points in time (e.g., when new images become available). An important aspect is blinding of the time sequence. The sets of images per patient can be offered to the reader with information on which image belongs to baseline and which to follow-up

dates. However, in most trials the dates of the images are also blinded. Scoring in chronologic order can be feasible, such as in observational cohorts in which new annual follow-up images become available. If scoring in a blinded time order, each new radiograph would mean a new scoring of all the images. In the case of scoring with a known time sequence, scoring of new images is performed with the baseline and two previous images presented at the same time as the scores of the previous scoring session.

In clinical trials, scoring with a blinded time sequence is preferred because it avoids bias, although errors such as nonexistent repair of erosions may result. Moreover, most statistical tests require that scoring errors be equally likely to occur in both directions (overscoring and underscoring), which is the case with blinded reading. This is also a prerequisite for the proposed assessment of possible repair in a trial arm. Finally, regulatory agencies in both the United States and Europe require that the order of images be blinded.

Presentation of data

For each trial, information on mean and median values (with appropriate assessment of variation) should be presented because both give additive information. Moreover, graphic representation of all the individual patient data in a so-called cumulative probability (or frequency) plot shows all the information in a comprehensive manner.⁴ In a probability plot the scores per group (usually the change scores over a defined period) are ordered from the lowest to the highest (Fig. 45.2). This provides an opportunity to appreciate the full range, the median, and the corresponding value for every percentile that one might be interested in. The plot can also be used to determine the percentage of patients showing progression above a certain limit. Preferred cutoffs can be applied. This methodology is much more powerful than simply representing patients as being above 0.5 (if the average of two readers is being used), above 0 (if one reader is used), or above the SDC. Moreover, the coherence of the data can be appreciated, and it illustrates the prevalence and influence of outliers well.

Statistical handling of missing data

Missing data are a significant issue in clinical trials, especially with long-term follow-up. This pertains to clinical as well as imaging data. However, how to deal with missing imaging data is fundamentally more challenging. Theoretically, clinical data on follow-up have three options: no change, improvement, or worsening. Structural damage, however, is largely irreversible; consequently, only two options are in fact available: no change or worsening. Moreover, in most trials there is preferential dropout in the comparator arm of the trial (either placebo or the frequently less effective standard treatment). In case of inefficacy, this is usually based on clinical data: a high level of disease activity. By applying the technique of last observation carried forward (LOCF), this high level of disease activity is captured in the analysis of clinical efficacy data. Also, the imputation of a nonresponder status in the clinical analysis provides the correct information that this patient did not respond well to treatment. However, application of the

Fig. 45.2 On the y-axis the cumulative frequency plot shows the change in total score of the Sharp method, with the scores of all individual patients being depicted as diamonds. These scores are ordered from the lowest to the highest and are presented on the x-axis as cumulative frequency. If you want to read the 10th percentile, you draw a line starting at 10% cumulative frequency and connect it where it crosses the figure on the y-axis. The corresponding score on the y-axis (−0.4) can be read. Similarly, the 90th percentile corresponds to a change in score of 3.6, and the median is a change of 0. You can also start with a certain change in score (e.g., +2.0) and read the corresponding percentage on the x-axis: 76% of the patients show a change in score of 2.0 or less. The magenta lines indicate scores belonging to percentiles; the orange line indicates the percentage of patients belonging to a certain score.

LOCF technique to imaging data underestimates actual progression because it might be expected that it is more likely that these patients will show worsening than no change. Responder data are not frequently used for imaging, certainly not as a primary endpoint, because this greatly decreases the power of a trial. The most widely used “best approach” is linear extrapolation of the progression. To be able to apply this technique, at least a baseline film and one follow-up film need to be available. Although progression in individual patients is not always linear, it is on a group level and suffices for analysis of structural damage data. With the use of early-escape trial designs, the control group frequently has only a short follow-up before being switched to the open label of the treatment under investigation. With the primary endpoint for imaging being at 24 or 52 weeks and early escape between 12 and 16 weeks, linear extrapolation is an important aspect in analysis of the data. In trials with treatment that suppresses structural progression effectively, progression in the control arms determines the power of the study. Such progression can be detected only in the first 12 to 16 weeks until early escape for patients who choose this option, which might be a very high number as shown in recent trials. It has been demonstrated that radiographs are sufficiently sensitive to detect changes over a 12- to 16-week period. It should be stressed that it is crucial to obtain follow-up radiographs in all patients regardless of premature discontinuation and to limit data imputation as much as possible.

Missing data on individual joints need to be handled within the same joint group. For example, if data on metacarpophalangeal (MCP) joints are missing, these data will be substituted by data from the remaining MCP joints. The imputation is based on progression scores. Most frequently, missing up to 20% to 30% of the joints in a particular joint group is accepted before the entire time point is set as missing.

Statistical analysis

For the primary analysis, the average of two readers is used. The scores of single readers can be applied as sensitivity analyses. Because radiographic progression is typically not normally distributed, nonparametric testing should be applied. The primary endpoint is the change in progression (extrapolated if necessary) based on the average score of two readers. This can be done by several parametric and nonparametric methods, but an

analysis of covariance (ANCOVA) using the ranks of change with factors at baseline that are expected to influence structural progression is frequently performed. The baseline structural damage score is such a factor. Mixed-effect modeling is another way to analyze the data; it allows longitudinal interpretation (development in time) of the data because it uses all time points instead of only one predefined endpoint. Under certain conditions, mixed-effect models provide more statistical power. Both ANCOVA and mixed-effect models can be fit to raw scores, as well as be used after logarithmic transformation.

To confirm the robustness of the data an LOCF analysis can be performed, although it should be realized that statistical significance might be lost.

Minimum duration of trials

It has been demonstrated that effects can already be demonstrated after 6 months and even after 3 to 4 months. Thereafter, it is important that the gain obtained in the first 6 months be maintained over the second 6 months and ultimately over the second year. Currently, structural damage, as assessed on radiographs, is considered the “gold standard.” The challenge with the early-escape design is the length of duration of the control arm. It is being accepted more and more that if the difference obtained during the period with a control arm is sustained over the follow-up period, this is sufficient to fulfill the required longer follow-up period. In practice this means that a significant difference at week 24 (with or without extrapolated data), with maintenance of the difference between the originally randomized trial arms over the next half-year or over the next 18 months (or both), is sufficient for filing. However, this needs to be discussed with the agencies for each trial specifically.

Placebo versus active comparator

True placebo arms with a sufficiently long follow-up to assess structural damage are no longer accepted for ethical reasons. The closest to such assessment is the partial-responder trial design in which patients who still have active disease are randomized to continue receiving the same treatment with placebo added or with the treatment under investigation added. Also

in this situation, only short periods of follow-up are accepted to be ethical, and patients have the opportunity to opt for early escape at a fixed time of follow-up, usually between 12 and 16 weeks. Until now this was sufficient to detect change in the control arm. There is, however, a trend of including patients in trials with less active and less severe disease. Consequently, progression in the control arm is smaller, which necessitates larger trials to maintain the same power. It is thought that alternative trial designs are needed.

Repair

Although most emphasis is on detection of progression of structural damage, over the past decades it has become apparent that repair of damage is also possible. This could be observed in individual joints and patients but also in studies specifically designed to test the concept of repair, as well as on the group level in clinical trials. By definition, there is proof of repair on a group level if the mean change over time, including the 95% confidence interval, is below zero, which indicates that the group had statistically significant improvement. Determining definite repair in an individual joint or patient is more difficult. Based on data obtained in a trial,^{4a} there is circumstantial evidence that repair is a real phenomenon because it is almost exclusively observed in joints without swelling, can be reproduced in independent reading sessions, and is prevalent predominantly in patients treated with tumor necrosis factor blockers.

RHEUMATOID ARTHRITIS

Conventional radiography *Films of the hands and feet*

Structural damage, especially erosions, is frequently present in the joints of both the hands and feet. Moreover, these are the sites that structural damage can easily be detected because of the size of the joints. Importantly, these sites show the first erosions, and erosions are even more frequent in the feet than in the hands. The wrist is the joint most predisposed to early JSN. Therefore it is recommended that films of the hands and feet always be taken. By doing so a large number of joints are available for evaluation. It is not necessary to routinely take films of the large joints for assessment of the course of disease because it has been demonstrated that damage in the small joints is representative of damage in the large joints. Important in this respect is that patients with normal radiographic findings in the hands and feet do not have structural damage in any of the large joints.⁵

For scoring it is sufficient to take films of the hands in the posteroanterior view and the feet in the anteroposterior view. It is of utmost importance that positioning and technical aspects be standardized to ensure comparable images at follow-up. Additional views of the hands, such as the Nørgaard or Brewerton (ball catcher's) views, are not recommended because it is hard to standardize and obtain comparable images over time.

Scoring methods

Information from radiographs can be used as an outcome in clinical trials only if it is quantified. Several scoring methods discussed later in this chapter are available for this purpose. Selection of the most appropriate scoring method is largely dependent on the setting in which it will be applied. For example, in clinical practice and large cohort studies, feasibility is of major importance, whereas in clinical trials, sensitivity to change drives selection of a method.

The methods that have been used most frequently in recent research and clinical practice are described here. For a historical overview of all published scoring methods, readers are referred to the literature.⁶ Below, the methods of applying a global score, mainly based on the Larsen method, are presented first, followed by presentation of the more detailed scoring methods. An overview of the various characteristics of the scoring methods, such as the joints and features included, the range per joint, and the total score, is presented in Table 45.1.^{7,8}

Because erosions and JSN are reflections of different disease processes, it is advantageous to score these features independently, which is done in the detailed scoring methods. This opens the possibility of assessing a differential effect of specific treatment on bone versus cartilage.

Global assessment per joint

Larsen score

The Larsen score applies a grade from 0 to 5 to individual joints.⁹ This method is the only one that can be applied to both large and small joints,

and a reference atlas with grades for the various joints is available. The scoring is a combination of mainly erosions and JSN, and it results in a global grade. The original Larsen scoring method included soft tissue swelling and juxtaarticular osteoporosis in grade 1. Only from grade 2 onward are definite structural abnormalities such as erosions present. Grade 5 represents mutilating abnormality. Several modifications of the scoring system have been published by the authors, with the most important modification being that for use in longitudinal studies. Most studies include only the joints of the hands, wrists, and feet. The information in Table 45.1 is based on the original method applied to the hands, wrists, and feet. Originally, the wrist was evaluated as a single joint. In total, 32 joints are scored, which leads to a scoring range for the hands and feet of 0 to 160. The modification published by Larsen and associates in 1995 changed both the sites to be evaluated and the grading. Most striking is the deletion of soft tissue swelling and osteoporosis for grade 1.¹⁰ Now, erosions less than 1 mm and slight JSN are graded as 1. The number of areas in both the hands and feet has been changed. The interphalangeal (IP) and MCP joints of the thumb are no longer included, nor are the IP and metatarsophalangeal (MTP) joints of the big toe. In this modification the wrist is scored in quadrants. Therefore the number of joints assessed remains 32.

Scott modification of the Larsen method

The modification by Scott and coworkers is frequently used when the "Larsen" method is applied.¹¹ These researchers redefined the grading and applied it to the same 32 joints as in the original Larsen method. Moreover, the wrist is scored as a single joint but is weighted by a factor of 5 to obtain the total score. This brings the range for hands and feet from 0 to 200.

Ratingen score

In this modification of the Larsen score, grading is based entirely on the surface area of the joints destroyed by erosions.¹² This is graded from 0 to 5 (grade 1, <20%; grade 2, 21% to 40%; up to grade 5, >80% destroyed). In total, 38 joints of the hands are scored, which results in a range of 0 to 190.

Detailed scoring methods

Sharp method

The Sharp method is the first published method that described a detailed scoring system for erosions and JSN separately for joints in the hands and wrists. The Sharp method that is used at present is in fact the modification described in 1985.¹³ The number of joints scored was reduced from 27 originally for both erosions and JSN to 17 for erosions and 18 for JSN per hand.

Moreover, the method was developed and validated for scoring the joints of the hands, but at present the same methodology is also applied to the joints of the feet. Erosions are scored from 0 to 5 per joint and are counted when discrete, and surface erosions are scored according to the surface area involved. JSN is scored on a scale of 0 to 4: focal narrowing (score of 1), joint space loss of less than 50% (score of 2), joint space loss of greater than 50% (score of 3), and complete joint space loss or ankylosis (score of 4). Subluxation or luxation is not included in the score. The erosion score and the JSN score can be used separately but are usually summed to obtain a total score (range for hands: 0 to 314).

Genant modification of the Sharp method

A modification of the Sharp method was described by Genant in which the scale for progression was extended from a 6-point scale to an 8-point scale with 0.5-point increments from 0 to 3+ for erosions and from a 5-point scale to a 9-point scale with 0.5-point increments from 0 to 4 for JSN.¹⁴ This score is applied to 14 joints of each hand and wrist for erosions and to 13 joints for JSN. It results in a total score range of 0 to 202 for the hands. Frequently, this is normalized to a 200-point scale. If the feet are scored, this is applied to the five MTP joints and the IP joint of the first toe. The maximum score for the hands and feet is 292, frequently normalized to 290.

van der Heijde modification of the Sharp method

The main modification by van der Heijde was the addition of six joints per foot (five MTP joints and the IP joint of the first toe) to the scoring system. Moreover, two sites for erosions and two sites for JSN were deleted from the scoring areas outlined in the Sharp method in 1985, which leaves 16 sites for erosions and 15 for JSN per hand.¹⁵ Scoring of erosions in the hands remained the same, with a range of 0 to 5 per joint. However, for scoring of erosions in the feet the scoring range was expanded to 10 per joint, with a maximum of 5 for the metatarsal and phalangeal sites of the joint. Another major difference is that subluxation and luxation (malalignment) are integrated into the grading of JSN. JSN is scored on a scale of 0 to 4, with the same grading as described for the Sharp method, but in this modification a

score of 3 can also be applied in the case of subluxation of a joint and a score of 4 in the case of complete luxation. These features are scored mostly in the MCP and MTP joints. The range for the total score is 0 to 448. An example of scoring the MCP joints is presented in Figure 45.3.

Figure 45.4 shows a comparison of the sites in the hands included in the Sharp method, the van der Heijde modification of the Sharp method, and the Genant modification of the Sharp method. The major differences are in sites in the wrist, both for erosions and for JSN. Table 45.2 shows weighting of the erosions and JSN scores in the three scoring methods. The Genant scores apply a normalization, and thereafter the weight for erosions and JSN is equal. The van der Heijde modification has the largest weight on erosions, whereas for the Sharp method the weight is intermediate.

Simple Erosion Narrowing Score

This method is based on the joints included in the van der Heijde modification of the Sharp method for the hands and feet. Instead of scoring the joints for erosions and JSN, the number of eroded joints and the number of narrowed joints are simply counted.¹⁶ A score of 1 is applied if a site is eroded and also per narrowed site. In total, 15 joints per hand are scored for erosions and 16 for JSN and 6 joints per foot for both erosions and JSN, which results in a scoring range of 0 to 86.

Magnetic resonance imaging and ultrasonography

Conventional radiography, despite being the most widely used imaging method for assessing structural damage in RA, has limitations. It does not

Fig. 45.3 Scores according to the van der Heijde modification of the Sharp method for grading erosions and joint space narrowing in the metacarpophalangeal and interproximal phalangeal joints of the left hand. The arrows indicate the location of an erosion; the number indicates the score of the erosion. The sum of the erosions per joint is depicted as "E." The score for joint space narrowing per joint is presented as "N." The interproximal joint is not scored for joint space narrowing.

Fig. 45.4 Sites in the hands included in the Sharp method (a), the van der Heijde modification of the Sharp method (b), and the Genant modification of the Sharp method (c). The green areas indicate sites for scoring joint space narrowing and the red areas indicate sites for scoring erosions.

JSN, joint space narrowing.

visualize the earliest stages of bone erosion. In contrast, MRI and ultrasonography allow direct visualization of the early destructive joint changes in RA. For ultrasonography, no widely accepted scoring methods are available for use in clinical trials, although validation of several methods is under way.¹⁷ For MRI, the RAMRIS (RA MRI scoring system) is the validated scoring method of choice. It is a semiquantitative assessment of synovitis, bone erosions, and bone edema in the hands and wrists.¹⁸ A minimum set of MRI sequences (Box 45.1), as well as a consensus MRI definition of important joint pathologic processes (Box 45.2), were also suggested. An atlas with reference images for scoring is available. The main features of the RAMRIS are presented in Box 45.3.

Magnetic resonance imaging sum scores

Sum scores for synovitis, erosion, and edema can be calculated by summation of the individual joint scores, as a total sum, or separately in the evaluated wrist and second to fifth MCP joints. For synovitis, the possible range of the sum scores of the unilateral second to fifth MCP joints, wrist joint, and both are 0 to 12, 0 to 9, and 0 to 21, respectively. Corresponding values for bone erosion are 0 to 80, 0 to 150, and 0 to 230, whereas for bone edema they are 0 to 24, 0 to 45, and 0 to 69.

PSORITIC ARTHRITIS

Conventional radiography

Typical lesions and site of lesions

Although PsA has similarities with RA, there are also major differences in the type and site of lesions, as well as in the joints involved. Whereas RA is characterized by mainly osteodestructive lesions, PsA has both osteodestructive and osteoproliferative manifestations that may even coexist not only in the same patient but even in the same joint. Characteristic radiographic features of PsA include joint erosions, JSN, and bony proliferation, including periarticular and shaft periostitis, osteolysis, ankylosis, spur

BOX 45.1 MINIMUM SET OF BASIC MAGNETIC RESONANCE IMAGING SEQUENCES

- Imaging in two planes* with T1-weighted images before and after intravenous administration of gadolinium[†]
- A T2-weighted fat-saturated sequence or, if this is not available, a short tau inversion recovery (STIR) sequence

*Imaging in two planes can be achieved by obtaining a two-dimensional sequence in two planes or a three-dimensional sequence with isometric voxels in one plane to allow reconstruction in other planes.

[†]Intravenous injection of gadolinium is probably not essential if destructive changes alone (bone erosions) are considered important.

Reproduced with permission from Østergaard M, Peterfy C, Conaghan P, et al. OMERACT Rheumatoid Arthritis Magnetic Resonance imaging Studies: core set of MRI acquisitions, joint pathology definitions, and the OMERACT RA-MRI scoring system. *J Rheumatol* 2003;6:1385-6.

formation, and spondylitis. Abnormalities are seen in the phalangeal tufts and at sites of attachment of tendons and ligaments of the bone. Although the erosive changes in early PsA are marginal, as in RA, they become irregular and ill defined with progression of disease because of periosteal bone formation adjacent to the erosions. In severe cases, erosive changes may progress to the development of a “pencil-in-cup” deformity or gross osteolysis. These features are typical of arthritis mutilans.

Joint involvement in PsA is often asymmetric and may be oligoarticular. Asymmetric erosions may be visible radiographically in the carpus and in the MCP and proximal (PIP) and distal (DIP) IP joints of the hands, but the DIP joints are often the first to be affected. The hands tend to be involved much more frequently than the feet, with a ratio of nearly 2:1. Erosive changes and bone proliferation in the feet usually involve the IP and MTP joints; the IP joint of the first toe is most often affected. Radiographs of the

BOX 45.2 DEFINITIONS OF IMPORTANT RHEUMATOID ARTHRITIS JOINT PATHOLOGIC PROCESSES ON MAGNETIC RESONANCE IMAGING

Synovitis: An area in the synovial compartment that shows above normal gadolinium enhancement of a thickness greater than the width of normal synovium.

- Enhancement (increase in signal intensity) is judged by comparison of T1-weighted images obtained before and after the intravenous administration of gadolinium.

MRI bone erosion: A sharply margined bone lesion with correct juxtaarticular localization and typical signal characteristics that is visible in two planes with a cortical break seen in at least one plane.

- T1-weighted images show loss of the normal low signal intensity of cortical bone and loss of the normal high signal intensity of trabecular bone. Quick gadolinium enhancement suggests the presence of active, hypervascularized pannus tissue in the erosion.
- Other focal bone lesions, including metastases, must obviously be considered but are generally distinguishable by associated imaging and clinical findings.

MRI bone edema: A lesion within trabecular bone with ill-defined margins and signal characteristics consistent with increased water content.

- This may occur alone or surrounding an erosion or other bone abnormalities.
- Signal intensity is high on T2-weighted fat-saturated and STIR images and low on T1-weighted images.

MRI, magnetic resonance imaging; STIR, short tau inversion recovery.

BOX 45.3 RAMRIS SCORING SYSTEM

- **Bone erosions:** Each bone (wrists: carpal bones, distal radius, distal ulna, metacarpal bases; MCP joints: metacarpal heads, phalangeal bases) is scored separately. The scale is 0 to 10 and is based on the proportion of eroded bone in comparison to "assessed bone volume" as judged on all available images: 0 = no erosion, 1 = 1% to 10% of bone eroded, 2 = 11% to 20%, etc. For long bones, "assessed bone volume" is from the articular surface (or its best estimated position if absent) to a depth of 1 cm, whereas in carpal bones it is the whole bone.
- **Bone edema:** Each bone is scored separately (as for erosions). The scale is 0 to 3 and is based on the proportion of bone with edema: 0 = no edema, 1 = 1% to 33% of bone edematous, 2 = 34% to 66%, and 3 = 67% to 100%.
- **Synovitis:** Synovitis is assessed in three wrist regions—(1) the distal radioulnar joint, (2) the radiocarpal joint, and (3) the intercarpal and carpometacarpal phalangeal joints—and in each MCP joint. The first carpometacarpal phalangeal joint and the first MCP joint are not scored. The scale is 0 to 3. A score of 0 is normal, whereas scores of 1 to 3 (mild, moderate, severe) designate thirds of the presumed maximum volume of enhancing tissue in the synovial compartment.

MCP, metacarpophalangeal.

Reproduced with permission from Østergaard M, Peterfy C, Conaghan P, et al. OMERACT Rheumatoid Arthritis Magnetic Resonance Imaging Studies: core set of MRI acquisitions, joint pathology definitions, and the OMERACT RA-MRI scoring system. *J Rheumatol* 2003;6:1385-6.

hand are most important in the follow-up of patients, but the addition of films of the feet makes the picture more complete.

Scoring methods

The development and validation of scoring methods for PsA are less well worked out than for RA. All the methods used presently find their basis in scoring methods for RA. There are two global scoring methods and two detailed scoring methods, which are summarized in Table 45.3 and described below.

Global assessment per joint

Modified Steinbrocker score

This method was developed in the PsA clinic at the University of Toronto.^{19,20} Each joint is scored on a scale of 0 to 4: 0 = normal; 1 = juxtaarticular

osteopenia or soft tissue swelling; 2 = erosion; 3 = erosion and JSN; and 4 = total joint destruction, either lysis or ankylosis. This score is applied to 14 joints in each hand and 6 joints in each foot. The range of the score is 0 to 160.

Psoriatic arthritis Ratingen score

This method includes 40 joints in the hands and feet.^{20,21} All joints are scored separately for destruction and proliferation. The destruction score is based on the amount of joint surface destruction on a scale of 0 to 5: 0 = normal, 1 = one or more definite erosions with an interruption of the cortical plate of greater than 1 mm but destruction of less than 10% of the total joint surface, 2 = destruction of 11% to 25%, 3 = destruction of 26% to 50%, 4 = destruction of 51% to 75%, and 5 = destruction of greater than 75% of the joint surface. The proliferation score considers any kind of bony proliferation typical of PsA on a scale of 0 to 4: 0 = normal; 1 = bony proliferation of 1 to 2 mm measured from the original bone surface or, if the margins of the proliferation cannot be distinguished from the original bone surface, clearly identifiable bone growth not exceeding 25% of the original diameter of the bone; 2 = bony proliferation of 2 to 3 mm or bone growth between 25% and 50%; 3 = bony proliferation greater than 3 mm or bone growth greater than 50%; and 4 = bony ankylosis. The destruction score with a range of 0 to 200 and the proliferation score with a range of 0 to 160 are summed to give the total score (range of 0 to 360).

Detailed scoring methods

Psoriatic arthritis scoring method based on the Sharp scoring method for rheumatoid arthritis

The erosion scale used for RA has a range of 5 per joint. Scores are applied as 0 = no erosion, 1 = one discrete erosion or involvement of less than 21% of the joint area by erosion, 2 = two discrete erosions or involvement of 21% to 40% of the joint, 3 = three discrete erosions or involvement of 41% to 60% of the joint, 4 = four discrete erosions or involvement of 61% to 80% of the joint, and 5 = extensive destruction involving more than 80%.^{20,22} The erosion scale was expanded with the scores 6 and 7 to accommodate the more extensive bone destruction seen in many cases of PsA, such as gross osteolysis or a "pencil-in-cup" lesion. However, scores of 6 and 7 are not added to obtain the total erosion score; instead, these features are kept separately. The erosion score is applied to 21 joints in each hand and to 6 joints in each foot, which results in a range of 0 to 210 for the hands and 0 to 60 for the feet. Scoring of JSN is on a scale of 0 to 4 as used for RA. The JSN scores are 0 = normal joint; 1 = asymmetric or minimal narrowing; 2 = definite narrowing with loss of up to 50% of the normal space; 3 = definite narrowing with loss of 51% to 99% of the normal space; and 4 = absence of a joint space, presumptive evidence of ankylosis. A score of 5 is added in the case of widening, which is automatically scored when gross osteolysis is present. Again, the score for widening is not included in the total narrowing score but is analyzed as a separate feature. The JSN score is applied to 20 joints in each hand and 5 joints in each foot, which results a range of 0 to 160 for the hands and 0 to 40 for the feet.

Sharp-van der Heijde modified scoring method for psoriatic arthritis

A similar scoring system as used for RA is applied to PsA.²⁰ The same joints are scored for erosions and JSN, with the addition of the eight DIP joints for erosions and the eight DIP joints and two IP joints of the thumb for JSN. Again, the maximum score for erosions is 5 in the joints of the hands and 10 in the joints of the feet. Scores for erosions are applied as follows: 0 = no erosion, 1 = discrete erosion, 2 = large erosion not passing the midline, and 3 = large erosion passing the midline; a combination of these scores may lead to the maximum of 5 per entire joint in the hands and 5 at each site of the joint (a maximum of 10 for the entire joint) in the feet. The so-called JSN score is based on the following features: 0 = normal; 1 = asymmetric or minimal narrowing up to a maximum of 25%; 2 = definite narrowing with loss of up to 50% of the normal space; 3 = definite narrowing with loss of 50% to 99% of the normal space or subluxation; and 4 = absence of a joint space, presumptive evidence of ankylosis or complete luxation. Gross osteolysis and "pencil-in-cup" lesions are scored separately. In the final summary score, joints with one of these abnormalities receive the maximum score assigned for both erosions and for JSN. The total maximum score for erosions is 200 for the hands and 120 for the feet; the total maximum score for JSN is 160 for the hands and 48 for the feet. The total maximum erosion score is 360, the total maximum JSN score is 168, and the total maximum score is 528.

Magnetic resonance imaging and ultrasonography

Both MRI and ultrasonography have not been widely applied in PsA, although similar advantages as described for RA and AS can be expected.

No generally accepted or validated methods for assessment of PsA activity or damage exist. Recently, an OMERACT PsA scoring system (PsAMRIS) has been developed for use in hands with PsA, including discussions on appropriate MRI sequences and consensus definitions of important pathologic processes.²³ The scoring system needs further testing and validation in longitudinal studies.

ANKYLOSING SPONDYLITIS

Conventional radiography

Scoring methods

Three methods have specifically been designed for assessment of the structural damage in AS. An overview of the various characteristics of the scoring methods is presented in Table 45.4. All the methods are suitable to assess damage in the spine. In addition, scoring methods for the sacroiliac joints exist, as well as one specific method for assessment of the hips in AS.

Global assessment of the spine

Bath Ankylosing Spondylitis Radiological Index

The Bath Ankylosing Spondylitis Radiological Index for the spine (BASRI-spine) has three components: the lumbar spine, the cervical spine, and the

sacroiliac joints.²⁴ To assess the lumbar spine, lateral and anteroposterior views are used. The score for the lumbar spine, from the lower border of T12 to the upper border of S1, is a composite score of both views that takes all the affected levels into account in deriving the score. The cervical spine was defined as extending from the lower border of C1 to the upper border of C7. A global score ranging from 0 to 4 (normal, suspicious, mild, moderate, and severe) is applied to both the lumbar and cervical components. The grades are summarized in Table 45.5. Squaring, sclerosis, erosions, syndesmophytes, and fusion are the features included. Syndesmophytes and fusion are the most important features driving the scoring method. The sacroiliac joints are scored according to the four grades of the modified New York criteria. The BASRI-spine is the sum of the mean scores of the right and left sacroiliac joints (in one decimal) plus the score of the lumbar spine and the score of the cervical spine. The range for the BASRI-spine is 2 to 12 (because patients with AS have sacroiliitis by definition, the minimum score is 2). A similar grading system has been developed for the hips: the BASRI-hip. The sum of the BASRI-spine and BASRI-hip is called the BASRI-total, which has a range of 2 to 16.

Detailed assessment of the spine

Stoke Ankylosing Spondylitis Spine Score

The Stoke Ankylosing Spondylitis Spine Score (SASSS) is a detailed scoring system for the anterior and posterior sites of the lumbar spine and includes

TABLE 45.4
Comparison of radiographic scoring methods for ankylosing spondylitis

*The maximum score per corner is 1; either erosion, sclerosis, or squaring can be scored.

[†]Four corners of six vertebrae are scored.

[‡]The two anterior corners of 12 vertebrae are scored.

[§]Without the hips, three sites (cervical and lumbar spine and sacroiliac joints) are scored; with the hips, four sites are scored.

^{||}Without the hips the range is up to 12; with the hips the range is up to 16.

BASRI, Bath Ankylosing Spondylitis Radiological Index; SASSS, Stoke Ankylosing Spondylitis Spine Score.

Reproduced with permission from van der Heijde D. Quantification of radiological damage in inflammatory arthritis: rheumatoid arthritis, psoriatic arthritis and ankylosing spondylitis. *Best Pract Res Clin Rheumatol* 2004;18:847-860.

the lower border of the 12th thoracic vertebra, all five lumbar vertebrae, and the upper border of the sacrum on a lateral view.²⁵ All four corners of each vertebra are examined and scored 1 if one or more of erosion, sclerosis, or squaring is present; scored 2 for a syndesmophyte; and scored 3 for total bony bridging; the maximum possible score is 72.

Modified Stoke Ankylosing Spondylitis Spine Score

This method is a modification of the SASSS in which the anterior site of the lumbar and cervical spine is scored on a lateral view.²⁶ The anterior site of the same vertebrae of the lumbar spine as described for the SASSS is scored, and the anterior site of the cervical spine from the lower border of the second cervical vertebra up to the upper border of the first thoracic vertebra is scored. Scoring of features is identical to that for the SASSS. The range is also 0 to 72. The modified SASSS has been selected as the preferred method for assessing structural damage in the spine by the Assessment in SpondyloArthritis international Society (ASAS) and the Outcome Measures in Rheumatology (OMERACT) based on favorable reproducibility and sensitivity to change in comparison to the BASRI and SASSS.^{27,28} An example of scoring the cervical spine is presented in Figure 45.5.

TABLE 45.5
BASRI grading of the spine in patients with ankylosing spondylitis*

Score	Grade	Description
0	Normal	No change
1	Suspicious	No definitive change
2	Mild	Any number of erosions, squaring, or sclerosis with or without syndesmophytes in ≤ 2 vertebrae
3	Moderate	Syndesmophytes on ≥ 3 vertebrae, with or without fusion involving 2 vertebrae
4	Severe	Fusion involving ≥ 3 vertebrae

*The scores are applied to the lateral cervical spine and to the lateral and anteroposterior lumbar spine combined. The scores for the sacroiliac joints are added to obtain the BASRI total score (range, 2 to 12).

BASRI, Bath Ankylosing Spondylitis Radiological Index.

Fig. 45.5 Scores according to the modified Stoke Ankylosing Spondylitis Spine Score of the cervical spine. The numbers are related to each corner at the anterior site of each vertebral body starting at the lower border of C2 to the upper border of T1. The vertebral body of C7 is indicated.

Magnetic resonance imaging and ultrasonography

MRI is a very important imaging modality for AS because of its ability to visualize inflammatory changes in bone and soft tissue. It is the most sensitive modality for imaging changes in the spine and sacroiliac joint. AS may also involve peripheral arthritis and enthesitis, which can also be visualized with MRI. Typical AS lesions of the spine that can be visualized with MRI include spondylitis, spondylodiskitis, and arthritis of the apophyseal, costovertebral, and costotransverse joints. Findings indicating active disease in the sacroiliac joints (sacroiliitis) include juxtaarticular bone marrow edema, capsulitis, and enhancement of the joint space after the administration of contrast medium, whereas visible chronic changes include bone erosions, sclerosis, periarticular accumulation of fatty tissue, transarticular bone bridges, and ankylosis. Enthesitis is also common and may affect the inter-spinal and supraspinal ligaments of the vertebral spine and the interosseous ligaments in the retroarticular space of the sacroiliac joints.

The majority of MRI studies of the sacroiliac joint have used only one imaging plane (semicoronal, i.e., parallel to the axis of the sacral bone). To be maximally sensitive for changes in the ligamentous portion of the sacroiliac joints, imaging in two perpendicular planes is required. This is particularly important when MRI is used for diagnostic purposes and probably less so when used as an outcome measure in trials. Similarly, the majority of MRI studies of spines with AS involve only sagittal images, which are not

optimal for visualizing changes in the apophyseal and costovertebral joints. The importance of such changes remains to be determined.

It is generally agreed that adequate MRI of the spine in AS, as for the sacroiliac joints, must include at least a T1-weighted sequence without fat saturation and a short tau inversion recovery (STIR) sequence in one plane. To what extent further sequences, including contrast-enhanced sequences or more planes, are needed is debated and depends on the goal of the examination.

Ultrasonography is not used for determination of outcome in clinical trials of AS.

Scoring methods

Several scoring systems for assessment of disease activity in the sacroiliac joints and spine have been proposed. They have been tested against each other by the OMERACT-ASAS MRI in AS group. They are described next, followed by a description of the few systems available for assessment of chronic damage.

Activity—spine

Three different scoring systems have been developed and validated: the Ankylosing Spondylitis spine Magnetic Resonance Imaging—activity (ASSpMRI-a) score, in which activity is graded from 0 to 6 per vertebral unit in 23 units²⁹; the Berlin modification of the ASSpiMRI-a score, in which activity is graded 0 to 3 per vertebral unit in the same 23 units³⁰; and the Spondyloarthritis Research Consortium of Canada (SPARCC) scoring system, in which only the 6 vertebral units considered by the reader to be

the most abnormal are scored, with additional points given for “depth” and high “intensity” of the lesion (Table 45.6).²⁹⁻³² In an OMERACT-ASAS multireader exercise, the feasibility, reliability, sensitivity to change, and discriminatory capacity of all three scoring systems in patients with AS were evaluated. The SPARCC method had the highest sensitivity to change, as judged by the Guyatt effect size, and the highest reliability, as judged by the interreader ICC, but the Berlin modification had the highest reliability if judged by the SDC.³³ All these methods perform well, and none were selected as a preferred method.³⁴

Activity—sacroiliac joints

Three main scoring approaches based on either global scores per quadrant or individual scores in consecutive semicoronal images through the joint have been proposed (Table 45.7).³⁵⁻³⁷ The presence and extent of bone marrow edema in the cartilaginous portion of the joint are the primary MRI features that are scored, although one method also scores inflammation in the joint space and the ligamentous portion of the joint.³⁵⁻³⁷ In an OMERACT-ASAS multireader exercise, agreement between readers and sensitivity to change were compared and found to be somewhat better for the most detailed scoring method (the SPARCC method).³⁸

Damage—spine and sacroiliac joints

The only method proposed for scoring the spine in AS is the Ankylosing Spondylitis spine Magnetic Resonance Imaging—chronicity (ASSpMRI-c) score, which grades chronic changes (sclerosis, squaring, syndesmophytes, and fusion) from 0 to 6 per vertebral unit in 23 units (see Table 45.6).³²

FS, fat saturated; Gd, intravenous injection of gadolinium-containing contrast agent; sag, sagittal; SI, sacroiliac; SPARCC, Spondyloarthritis Research Consortium of Canada; STIR, short tau inversion recovery; T1W, T1 weighted.

Two scoring methods for assessing chronic changes in the sacroiliac joints have been described but are not widely used. The first scores bone erosions and sclerosis at four osseous positions per joint (the iliac and sacral sides of the cartilaginous and ligamentous portions of the joints, respectively), as well as joint space width.^{35,37} The second method scores each

sacroiliac joint from 0 to 4 based on a global assessment of erosion, sclerosis, joint space width, and bone bridging/ankylosis (see Table 45.7). Validation of the methods for assessment of damage is limited, and their value has not yet been clarified.

PRINCIPLES OF MANAGEMENT

46

Arthritis patient education, health promotion, and team approaches to management

■ MAURA D. IVERSEN ■ NANCY SHARBY

- Good communication between patients and providers leads to a more accurate diagnosis and prognosis, enhances adherence to treatment, increases satisfaction with care, and improves health outcomes.
- Patients' and providers' beliefs about medical care in general and arthritis care in particular have an impact on patients' perception of the quality of their care and their interest in adhering to medical interventions. Discrepancies between the health beliefs of the provider and the patient are a significant factor in health care outcomes and disparities and must be addressed when developing patient education.
- Adults approach learning with different perspectives and needs than children and teens do. They seek active engagement in learning, build on previous knowledge, and see the impact of learning on their lives.
- Health literacy is a significant component of patient understanding and adherence to medical therapy. Providers and educators need to acquire an array of skills to develop material that will address the needs of patients with low literacy levels.

Patient education is integral to the management of chronic diseases. In the broadest sense, education "is an activity undertaken or initiated by one or more agents that is designed to effect changes in the knowledge, skills and attitudes of individuals, groups or communities"¹ Patient education includes the provision of information; instruction in self-management skills, behavioral therapies, and motivation strategies; and techniques to enhance or develop social support for healthful behavior. Educational activities are essential to promote collaborative care. Patients have a right to receive information about their medical condition and the spectrum of treatment options available to them² and to actively engage in decision-making about their care.³ Patients who understand their condition and are knowledgeable about how and when to use their medications are more adherent to interventions and in the short term demonstrate improved health outcomes.^{3,4} Effective patient education programs are based on psychobehavioral theories and incorporate techniques designed to actively engage patients in their care and to enhance their problem-solving skills.⁵ They can be provided by one or more individuals involved in the patient's care and may occur in many settings (Table 46.1), beginning with the clinical encounter and expanding to public media. This chapter focuses on patient education and health promotion in various settings, evidence for the effectiveness of patient education, sample strategies, and the use of team approaches to the management of arthritis.

PATIENT EDUCATION DURING THE CLINICAL ENCOUNTER

Patient education begins the instant that the provider and patient encounter each other. The way that providers present themselves, including body language, tone of voice, word choice, and pattern of talk, influence the development of a trusting relationship⁶ and the manner in which information is received. Typically, the provider and patient enter the encounter with specific goals in mind, with a successful exchange being anticipated. The provider must establish rapport with the patient, formulate and convey a diagnosis and prognosis, explain the potential impact of the condition on the patient's life, listen to patient's ideas and concerns, and discuss treatment options. At the conclusion of the encounter, the patient and provider should have an established plan of care that is acceptable to both.

Good communication between patients and providers has many benefits. It leads to a more accurate diagnosis and prognosis, improves adherence to treatment,^{7,8} increases satisfaction with care,^{8,9} and improves health outcomes.⁸ Although physicians are not always comfortable counseling patients about their options and treatment choices, research demonstrates that these skills can be learned.¹⁰ Strategies such as sharing an assessment of the patient's understanding of the information, exploring patients' preferences and expectations of care, and actively listening to patients' concerns are essential for successful communication and education.¹¹⁻¹⁴

RESEARCH ON PROVIDER-PATIENT COMMUNICATION IN ARTHRITIS

Provider-patient communication studies focus on attributes of the participants, as well as on processes and outcomes of discussions. Patients' concerns extend beyond managing symptoms and medications to the social, emotional, and psychological effects of their disease. Physicians, however, may be unaware of the psychosocial and work issues affecting patients with arthritis and may fail to address these issues.¹⁴ Failure to elicit these issues increases the likelihood that the patient will raise concerns too late in the visit to be addressed.^{14,15} It is good practice to begin with simple open-ended questions such as "Tell me how things are going" or "Tell me about what you have been doing?" and then wait for a response before proceeding. Do not interrupt until the patient is finished. Although this technique might seem more time intensive, in fact it is not. Most patients provide 80% of the information that one needs to know in 2 to 3 minutes.¹⁵ This strategy provides an opportunity to address misconceptions, present information, identify barriers to adherence, and suggest strategies to overcome these barriers, including information on available resources (e.g., community exercise, self-management programs).

TABLE 46.1
Settings for arthritis patient education

Setting	Type of patient education
Medical office visit	Patient education delivered by physicians as part of the medical consultation
Surgical or hospital unit	Preoperative or perioperative education for patients with arthritis undergoing joint surgery (may be individual or small group) or with other serious conditions
Outpatient or community interdisciplinary health care team	Patient education delivered by an individual or a team approach involving allied health professionals; it often includes physical therapists, occupational therapists, nurses, pharmacists, and health educators. This occurs in many community settings, outpatient clinics, and hospital settings. It may be conducted in either individual or small-group settings or in single or multiple sessions
Media	Broad programs reaching a wide target audience and consisting of other forms of arthritis education, such as books, pamphlets, brochures, written self-instructional material, audiovisual material, computer-assisted learning, and Internet resources
Population-based resources	Dissemination of public education via mass media campaigns and activities and support group development and activities carried out by national arthritis foundations, societies, and the Centers for Disease Control and Prevention (Arthritis Action Plan, Physical Activity Campaign, etc.)

Patient expectations about clinical discussions along with treatment expectations have important effects.¹³⁻¹⁷ Unfortunately, provider and patient expectations of the medical encounter may differ. In a survey of rheumatology patients, Rao and associates¹² noted that 33% were not satisfied with their clinical visit. Nearly half reported unmet expectations with regard to general information and 31% with respect to information about new medications. Patients' expectations of the efficacy of treatment also influence outcomes. In one study, patients' preoperative expectations of function and pain relief after spinal surgery influenced their pain and function up to 6 months after surgery.¹⁷ Clinical discussions inform patients of the purpose of treatments, as well as how and when to take medications or engage in exercise. Unfortunately, patients often misunderstand this information. A study of first visits to an arthritis clinic found that 15% of patients failed to understand the purpose of their prescriptions. They were less likely to be adherent to medication after 4 months than were patients who understood the purpose of the medication.¹⁶ Information on how to take medications properly, their side effects and benefits, and whether a latency period exists before the drugs take effect is also necessary for understanding and adherence to therapy. Unfortunately, most patients forget about 50% of the medical instructions in a very short time.¹⁶ Fraenkel and colleagues³ showed that use of a decision tool for disease-modifying antirheumatic drug (DMARD) therapy successfully improved knowledge and the likelihood of making an informed choice. To enhance patients' understanding of medical advice and adherence, information should be provided in simple, nonthreatening language along with clear written instructions. Pharmacists can also be engaged in these conversations either by their presence at the location of the health encounter or as an asset that patients can be taught to access at their local pharmacy.

Studies of patients' preferences for medications have helped elucidate issues related to adherence to drug therapy.¹³ For example, perceptions about the need for medications and fear of medication overuse influence adherence more than medical demographic factors do. Data suggest that Latino patients may be reluctant to use medications and might prefer to use herbal therapies.¹⁸ Both patients' and providers' beliefs affect the quality and outcome of the clinical encounter. They affect how patients interpret information and perceive how they are treated during visits, how much information they recall, and what they do with the clinical advice.^{6,16} Providers' beliefs and attitudes toward treatments influence the content of discussions and the likelihood of receiving a prescription.¹⁹ Thus, each contact needs to be individualized to develop the best plan of care.

Patients' desire for participation in decision-making is not routinely recognized by providers and may vary depending on their circumstances.^{11,20} In a cross-sectional study of 420 arthritis patients who were taking DMARDs or a biologic agent, Lim and coauthors⁵ reported that only 64% were satisfied with their level of participation in the decision-making process. Communicating information about risks in understandable terms^{3,21} and clarifying patients' beliefs and attitudes toward treatments and preferences for participation in decision-making are crucial. Even patients who would rather be passive during clinical discussions are more satisfied with their providers when they participate more fully in negotiations about disease management.²⁰

DESIGNING PATIENT EDUCATION PROGRAMS

Patient education is well grounded in behavioral change theory, which is derived from a range of disciplines, including psychology and the principles of adult learning. Theory-based approaches, including cognitive-behavioral and self-management programs, hold the most promise for successful arthritis education.²² Social learning theory posits that health-enhancing behavior results from the interplay between physiologic, social, and physical factors, as well as individuals' cognition about their disease.²³ This approach integrates program components often applied in isolation, such as cognitive-behavioral change strategies and a self-management framework.²³ A key cognitive dimension is self-efficacy, or an individual's situation-specific confidence in performing a task. Perceptions of the possible consequences of performing or not performing a behavior are also key to adoption of suitable health behavior.²³ Improving self-efficacy frequently leads to increases in appropriate health behavior and health outcomes.²²⁻²⁴

Conducting a needs assessment is the first step in developing effective education and personalized care of patients with arthritis.²² A needs assessment is the process of defining patients' knowledge, skills, resources, motivation, and barriers to effective management that influence their response to their illness.⁴ Patients with a chronic condition such as arthritis seek something to blame their disease on and develop construct models of illness to explain their symptoms. They describe and conceptualize their disease and symptoms in terms of their lives, their understanding of how their bodies work, their social networks, and the mass media.

HEALTH EDUCATION AND THE ADULT LEARNER

Traditionally, adults have been taught by instructional methods and philosophies developed for youth. However, adults approach learning with different perspectives and needs that must be considered when developing instructional material. Knowles, Holton, and Swanson, in *The Adult Learner: The Definitive Classic in Adult Education and Human Resource Development*,¹ provide strategies for how this can be accomplished. In essence, as people age, they develop along different life trajectories, so a group of adult learners will have more differences than the same-sized group of adolescents. Values, beliefs, level of education, life experiences, readiness to learn, goals, motivation, and learning styles will vary widely. Adult learning is driven by a need to know and a priority for information that will be immediately useful. "Hands-on" or active learning activities are the most successful, especially when they match the learner's readiness to learn. An effective learning strategy is the "teach-back" method in which instructors ask learners to describe what they will do when they get home based on what was discussed.²⁵ To initiate this exchange, the provider might say, "We have talked about a lot of things today and I know it can be difficult to remember everything. Can you tell me what you learned from today's visit and how you will take your new medication?" Depending on the patient's response, the provider acknowledges that the information was conveyed correctly or offers clarification.

In patient education and self-management programs, skills are taught through practice, modeling, group problem solving, and interactive discussions. Peer leaders often role-model behavior. Small-group programs usually consist of 6 to 10 members to allow time for individual needs, as well as group processes. Groups composed of patients with similar conditions and needs allow discussion and cross-fertilization of ideas and skills.²⁶ Program length, learning objectives and goals, and selection of leaders are important considerations. Short-term self-management programs enhance knowledge and skills, although these skills may diminish with time.²⁶ Periodic reinforcement is suggested to maintain skills and appropriate behavior. A mix of caregiver-based individual counseling and small-group education is optimal.

TABLE 46.2
Arthritis patient education content

Content area	Examples of specific content
Knowledge	Anatomy, disease process, inflammation Symptoms and signs and changes in severity of disease Importance of disease monitoring Pharmacologic therapy: use, effects, side effects, alternative therapy, when to change dosages of medication Benefits of surgical intervention Podiatry Nutrition, diet, and hazardous diets; weight control Community resources, helping agencies, potential assistance from government agencies Role of exercise, rest, joint protection skills, transcutaneous electrical nerve stimulation, acupuncture
Skills and behavior	Home exercise and physical activity programs Specific goal setting Modification of daily routines, domestic and leisure task management Self-monitoring or adherence Pain management: use of hot/cold, relaxation, other pain management behavior Work and occupational simplification (when possible) Stress monitoring and management
Problem solving (linked to self-management skills)	Communicating with health care providers Assertiveness, ability to ask questions, and negotiation of a shared plan of care Strategies for reducing anxiety, increasing confidence (self-efficacy), and reducing feelings of helplessness and fear Coping with the impact of chronic illness and depression Eliciting support from family, friends, and community members

CONTENT OF ARTHRITIS EDUCATION PROGRAMS

The major components of patient education programs include knowledge transfer, behavioral change and skill development, and psychosocial counseling (Table 46.2). The goals are to help patients understand their diagnosis and prognosis, critically appraise new information, and seek resources. However, patient education alone does not result in cognitive or behavioral changes.²⁰ Therefore, most programs emphasize the development of self-management skills to promote and adapt behavior based on patients' symptoms and disease activity. Self-management skills may include the use of splints and adaptation of exercise in those with hot swollen joints. These skills are learned through observation, performance, and the practice and consequences of such behavior.^{22,23} For example, patients who exercise regularly report improved function and decreased joint pain and stiffness.

Psychosocial counseling seeks to help patients cope with their arthritis and to feel more confident about their ability to maintain an active social and functional lifestyle.²⁷ Recruitment and training of lay leaders with arthritis to conduct education programs has resulted in positive short-term psychological effects for participants and leaders.²⁸ On a psychosocial level, social support can play a significant role in generating positive feelings of physical and mental well-being.²⁷ Family members and significant others may also have a role in facilitating the understanding and recall of information.

Importance of health literacy and cultural considerations

Multiple forms of communication are used to educate patients. Unfortunately, low health literacy is common. More than a third of the U.S. population struggle to understand even basic health information; twice that number find it challenging to navigate the health care system.²⁹ Literacy is a crucial

aspect of the patient's profile inasmuch as poor literacy is correlated with poor health outcomes.³⁰ Health literacy can be defined as "the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions."^{29,31} Thus, a patient may not understand how to read a prescription label, when to call a care provider for help, or how to follow through on a home activity program. In a study of literacy among patients with rheumatoid arthritis,³² one in six were illiterate and struggled to understand patient education material and prescription labels. These patients also had significantly more hospital visits. A second study³³ designed to assess the reading level of 80 patients with rheumatoid arthritis reported that 10% had difficulty reading patient material and 31% scored at or below the ninth-grade reading level. These results are consistent with research indicating poor health, poor understanding of treatment, greater use of health services, and low adherence to treatment regimens by patients with limited literacy.³⁴ Most patient education material is written at an 11th-grade or higher level, but the average reading level of the general public is below the 8th grade.³⁴ The following strategies are recommended to enhance patient education and improve adherence to treatment:

- Speak in simple language, avoid medical jargon, and repeat instructions.
- When possible, hire staff members who are bilingual.
- Provide easy-to-read material in plain English (fifth- to eighth-grade reading level) with illustrations.³¹
- Include significant others or family members in discussions (with patient consent). However, do not ask these family members or friends to act as translators.
- Motivate and enhance patient self-efficacy by discussing the pros and cons of treatment and incorporating information acquired from patients about their perspective.
- Engage patients in problem-solving strategies to address potential barriers to adherence and help develop contingency plans for dealing with treatment failure.

Designing culturally relevant educational material is especially important in groups with low literacy because interpretation of illustrations and behavioral modeling may be particularly sensitive to cultural context.^{29,31} Zhang and Verhoef³⁵ examined illness management strategies among Chinese immigrants with arthritis and found that management strategies fluctuate between Western and traditional Chinese medicine. Western medicine was believed to be less effective than traditional medicine for chronic conditions such as arthritis. The importance of health literacy goes beyond just comprehension of written or spoken material. Patients must also be able to synthesize the information to solve complex problems. Health literacy is fundamental to the ability to engage in healthy behavior that lowers the risk for secondary complications. When patients feel empowered to make their own choices about being healthy rather than just having a prescribed set of interventions to follow, they are more likely to make good choices.²⁹

Social and cultural factors

Social, cultural, and environmental factors influence the manner in which care is provided and perceived.³⁴ As diversity increases, we can no longer expect that everyone will "be on the same page" when it comes to the kind of health care and health communication that they desire. These preferences for care are not mere niceties but are strongly associated with health outcomes and health disparities.³⁶ Congruence between the way that care is delivered and the patient's cultural beliefs is termed *culturally competent care*. It means that during the delivery of interventions, patient-provider interactions and patient education material must conform to the social and cultural beliefs that each patient brings to the encounter.^{36,37}

Use of the Internet for patient education

Delivering patient education and self-management advice through the Internet has received less formal evaluation. Generational acceptance of technology and multimedia approaches to patient education exist and are even embraced by some. They can be explored to better understand cost-effective and efficacious delivery modes. In a study assessing the acceptability of an Internet-based self-management program for adolescents with juvenile idiopathic arthritis, 36 children of various ages, disease severity, and subtypes were recruited from four pediatric centers and participated in focus groups.³⁸ These adolescents stated that a Web-based intervention was a promising avenue to improve accessibility and availability of self-management techniques, such as gaining control over their disease, developing social support, and learning to communicate with providers. However, in a study of 71

older adults with arthritis, Tak and Hong³⁹ reported that just 39% of older adults used the Internet to obtain information on arthritis and only 28% had a home computer.

An important consideration when referring patients to Internet sites is the quality of the material. Ansani and colleagues⁴⁰ evaluated the quality of Internet-based information on arthritis with a standardized rubric and reported that the quality varied widely. The best sources of information were located on websites with URLs having suffixes of “.gov” and “.edu.” Kim and associates⁴¹ examined the impact of Web-based arthritis information on arthritis patients’ knowledge and medical practice. First, they reviewed and scored websites based on authorship, type of publication, contents, and financial interests. Next, 257 Korean adults with arthritis and rheumatologists were surveyed about use of the information from these sites. Twenty-eight percent of patients reported that they searched for arthritis information on the Internet. Significant correlates of the use of Web-based information were younger age, being employed, and having a higher income and higher education. Ratings of the accuracy of Web-based information on arthritis did not differ between physicians and patients. However, only 16.1% of physicians believed that patients understood the content, and physicians’ attitudes were less positive than those of patients.

Evidence for the effectiveness of arthritis education programs

Patient education programs range from provision of information to the use of cognitive-behavioral strategies, exercise prescriptions, and psychosocial support. Variability in content, target populations, and disease conditions, duration, and frequency complicates systemic evaluation of programs. Systematic reviews include a mix of study designs, patient education definitions, and health outcomes or include heterogeneous patient populations with respect to disease. Patients with osteoarthritis or rheumatoid arthritis are most often included in patient education trials. Comparisons of patient education programs by diagnosis indicate differences in outcomes that are not consistent across studies. Notably, patient education programs with behaviorally based interventions appear to be more effective than instructional programs alone.⁴

A review of 31 randomized controlled trials of arthritis patient education was recently performed.⁴ Patient education was defined as an intervention that includes formal structured instruction on arthritis and ways to manage the disease, such as psychobehavioral strategies, exercise, biofeedback, or psychosocial support. The results indicated modest improvements in functional disability, joint counts, global assessment, psychological status, and depression in the short term (up to 2 months), but no difference at follow-up (3 to 14 months). Improvements in functional disability translated into a 10% improvement on the Health Assessment Questionnaire. This review is unique in that separate analyses were performed, depending on the type of intervention. The data indicated that behavioral interventions resulted in greater improvement than no intervention did. However, the overall quality of the trials was not very high.⁴ These results are similar to data from Warsi and colleagues,²⁴ who evaluated the outcomes of 71 trials and found small to moderate effects. Mulligan and coworkers¹² pointed out that randomized controlled trial may not be the best design for examining self-management programs. Few studies have examined the impact of arthritis education programs on health care use and costs.⁴³

Structured patient education programs based on commonly accepted principles of education and psychology and applied consistently by trained personnel produce small improvements in knowledge, behavior, physiologic measures, and health outcomes beyond the effects of medications.^{4,42} Effects tend to be strongest when programs include behavioral strategies. Well-designed patient education programs are effective and integral to arthritis management. A randomized controlled study examining the outcomes of a small arthritis self-management group versus tailored-print education found slightly better results for the tailored-print program in the first year but that the results attenuated over time.⁴⁴ This study suggests that well-designed, tailored material increases patient education and allows greater dissemination of information.

MULTIDISCIPLINARY TEAM ROLES AND APPROACHES TO MANAGEMENT

Arthritis team care improves health care delivery and outcomes.⁴⁵ The multidisciplinary team care concept began more than 50 years ago, before new pharmacologic approaches were introduced. The team care philosophy is to rely on each professional’s knowledge and expertise to maximally address patients’ needs. Scandinavian countries were the first to initiate the team

care approach. Multidisciplinary team care may be provided in the hospital or on an outpatient basis in regular or day care facilities.⁸

The notion of team care varies across the globe. *Team care* is defined here as care involving the patient and a health care provider plus at least one other health care provider or family member that incorporates a team approach to information sharing, decision-making, and goal setting. The team may include a primary care physician, rheumatologist, nurse practitioner, physical therapist, occupational therapist, social worker, psychologist, podiatrist, vocational rehabilitator, the patient’s family, and the patient. Although team composition varies, the central team member is the patient. For a team to be effective, members need to understand and respect each other’s role (Box 46.1) and be cognizant of the information that they have imparted to prevent communication breakdown, prevent overlap and omission of services, and maximize patient care. In theory, team care allows different professionals to motivate and reinforce learning and provide care across a range of patient care settings. Team functioning is important and is becoming a stronger emphasis in health professional education and training.⁴⁶

Although team care is prevalent in Europe, such is not the case in North America, partly because of budgetary constraints, shortages of health care professionals, and reimbursement issues. Consequently, innovative team care models have emerged, such as the clinical nurse-specialist model⁴⁷ and the primary therapist model.⁴⁸ In these models, extensions of clinical practice are promoted.^{46,47} Study results suggest that patients referred to a primary therapist might have better outcomes than those referred to receive

BOX 46.1 STRATEGIES FOR DESIGNING EFFECTIVE PATIENT EDUCATION MATERIAL

Interview patients about their needs:

- What do you feel that you know the most about?
- What would you most like to know?
- How do you best like to learn? Listening, reading, watching, doing, using the Internet, watching video/movies?
- Do you like to learn in groups or alone?
- What are your biggest concerns?

Interview patients about their health beliefs and needs.

Obtain demographic information about clients:

- Chart reviews.
- Public data (Centers for Disease Control and Prevention, Census Bureau).
- Determine the patient’s health literacy level.

Write for your reader:

- Create messages that are culturally relevant.
- Consider language, health beliefs and practices, gender roles, etc.
- Match content to health literacy levels.
- Use plain language and simple short sentences.
- Do not use medical jargon.
- Use the simplest tense.
- Use “must” to convey requirements.
- Avoid abbreviations.
- Avoid calling the same thing by different names (e.g., medicine, drug, therapy).
- Use “you” and other pronouns.
- Repeat the most important information more than once.
- Use the active voice.
- Use the appropriate tone—what does this mean.
- Do not talk down to your audience.
- Write in positive not negative terms.
- Avoid ALL CAPS—appears as though you are yelling at the person (especially true for Web formats).
- Keep subjects and objects close to their verbs.
- Place conditional words after the main thought (e.g., “Take 3 aspirin if you have pain more than 5 hours and are not taking another NSAID”—NOT “If you have pain more than 5 hours and are not taking another NSAID, take 3 aspirin.”)
- Complex information may be better presented in tables.
- Simple pictures and diagrams can be helpful.

NSAID, nonsteroidal antiinflammatory drug.

Adapted from Rudd R, Anderson JE. The health literacy environment of hospitals and health centers. Harvard School of Public Health: Health Literacy Website; 2010. Available at www.hsph.harvard.edu/healthliteracy/files/healthliteracyenvironment.pdf. Accessed September 2, 2012.

traditional therapy.⁴⁸ Studies of the use of health care professionals in extended clinical roles are promising and warrant further investigation.

PUBLIC HEALTH APPROACHES TO EDUCATION OF PATIENTS WITH ARTHRITIS

Increasing recognition of health education and health promotion as primary prevention is evident by the growing emphasis on public health approaches to the management of arthritis by the Centers for Disease Control and Prevention and the Arthritis Foundation. Public health approaches provide population-based programs that enable access to individuals to reduce social inequalities and promote health. Approaches include health care professional and physician training (Table 46.3), community education programs, environmental modifications, health policies, and the use of mass media to provide low-intensity but widely disseminated messages on arthritis.

Public health approaches engage in three levels of health promotion. Primary prevention activities prevent the development of a health condition. This would not be appropriate for rheumatology practices because patients already have a health condition. Secondary prevention involves conditions that occur as a result of the primary health problem. For patients with arthritis this may include weakness, deconditioning, and joint stiffness or tightness. This is often the focus of patient education but may need to be explained in terms that are meaningful to the patient. For example, weakness may have an impact on someone's ability to play on the floor with grandchildren or to garden. Tertiary interventions are treatments intended to reverse or manage the disease process. They may also help the patient participate in activities that are important. Referral to various rehabilitation professionals or surgery may be useful here (see Table 46.3).

A main objective of a public health approach to arthritis is to reach all segments of the population, including socially disadvantaged groups, those whose first language is not English, and those who cannot access specialist medical care. To educate patients with arthritis, we need to develop programs and material for the less common but serious varieties of rheumatic disease. Health care providers and patients must advocate for policies and programs that reach the majority of individuals in a cost-efficient and cost-effective manner. *Healthy People 2020* includes a section devoted to arthritis, osteoporosis, and back care.⁴⁹ The Centers for Disease Control and Prevention has a dedicated arthritis initiative. The Arthritis Prevention, Control, and Cure Act is legislation designed to provide public access to arthritis education.

THE FUTURE OF ARTHRITIS PATIENT EDUCATION

In coming years we will experience an expansion in the application and dissemination of technology-based arthritis patient education. New devices are being implemented to dispense patient education and provide reinforcement opportunities through personal digital assistants, home cable boxes, or cell phones. These systems convey an auditory or text signal to engage and empower patients to be active in their care. Newer technologies are expanding to allow remote monitoring of patients while improving communication and maintaining a high level of personalized care.

We will develop, adapt, and evaluate patient education programs for specific populations such as minorities, those with limited literacy,³⁴ and individuals with rare forms of arthritis. With increasing health care

TABLE 46.3
Health professional roles in patient education and treatment

Professional	Role in patient education (examples)
Nurse	Has a primary care role in explaining and demonstrating medication use, action, interactions, side effects, and medication administration devices
Nutritionist	Explains the role of diet, helps plan a healthy diet and individualize it for the patient, discusses "alternative" diets and their potential risks, and provides weight control strategies
Occupational therapist	Provides training in relearning or adapting routine activities of daily living, recreation, and leisure pursuits; use of assistive devices and functional aids; and joint support to immobilize joints
Pharmacist	Provides patient education about the effects and side effects of drugs, how to read prescription bottles and take medications, and when and how to modify drug regimens; monitors for possible drug interactions
Physical therapist	Evaluates clients' restrictions in activity, functional limitations, and participation in society. Designs static and dynamic exercises and aerobic conditioning programs to improve mobility, prevent contractures or weakness, and improve cardiovascular pulmonary health. Suggests modifications of physical activity during the active phases of disease, instructs in pain management strategies, and provides modalities when needed to reduce pain (e.g., transcutaneous electrical nerve stimulation). Provides general information and strategies on health and well-being
Physician	Explains the disease and its physiology, natural history, and the range of therapies available; the need for disease monitoring; and the place of intraarticular injection, surgery, and other interventions. In some countries this is the role of community general practitioners, especially for uncomplicated and prevalent conditions (e.g., osteoarthritis, osteoporosis) and for providing adjunctive care for complicated or multisystem disease
Psychologist	Provides counseling for anxiety and depression and aids in dealing with denial or disease crises and coping with relationships, sexuality, and stress or management
Social workers	Helps with "patients' rights" to treatment, arranging time off work, enabling support from caregivers in the family and from the community and government, and possibly providing individual or family counseling

constraints and rheumatology workforce issues, we must explore innovative models of patient care delivery and education, assess their cost-effectiveness and health benefits, define outcomes that reflect the learning process, and capture the psychosocial dimensions and skill developments anticipated with education.

Principles of rehabilitation:
physical and occupational therapy

■ SHAWN FARROKHI ■ NANCY A. BAKER ■ G. KELLEY FITZGERALD

- Rehabilitation is the process of enabling persons with impairments, limitations in activity, or disabilities that cause suboptimal participation in various life situations (self-care, work, recreation and leisure, or community life) to regain or obtain the capacity necessary to participate at an optimal level. Rehabilitation therefore requires determining the optimal level of function, identifying the barriers that prevent the individual from obtaining that level of function, and providing interventions that facilitate attainment of that optimal level.
- Rehabilitation interventions can be classified as either remedial or adaptive processes.
- Remedial rehabilitation works to *restore* or *establish* capacity or ability. It focuses on improving impairments in muscular strength and endurance, joint motion, cardiorespiratory fitness, balance and coordination, and cognitive function (depression, anxiety, fear, self-efficacy) and may also refer to retraining in lost skill sets, such as self-care, dexterity, and work skills.
- Adaptive rehabilitation works to *compensate* for lost or absent capacity or ability. It focuses on providing alternative or supplementary methods to perform a task or activity so that performance can be optimized. Adaptive rehabilitation includes the use of equipment that substitutes for lost capacity, teaching new methods of performing tasks that incorporate existing capacity, altering the environment to facilitate performance, and changing the requirements of the task.
- Most rehabilitation therapists use a combination of remedial and adaptive rehabilitation methods to obtain optimal function.
- Because rehabilitation is a multifactorial process, it will often require a multidisciplinary team approach to optimize restoration of function in people with rheumatologic disorders.

DEFINITION OF REHABILITATION

The United Nations defines rehabilitation as “a goal-orientated, time-limited process aimed at enabling an impaired person to reach an optimum mental, physical, and/or social level.”¹ Rehabilitation is the process of enabling persons with impairments, limitations in activity, or disabilities that cause suboptimal participation in various life situations (e.g., self-care, work, recreation, leisure) to regain or obtain the capacity necessary to participate at an optimal level. Rehabilitation therefore requires determining the optimal level of function, identifying barriers that prevent the individual from obtaining that level of function, and providing interventions that facilitate attainment of that optimal level.

**PATIENT-CENTERED APPROACH
TO REHABILITATION**

Because each patient with arthritis has a unique set of impairments and functional deficits, rehabilitation therapists should use a patient-centered approach to determine an optimal level of function for every individual patient, depending on what that person *needs* and *wants* to be able to do.

Once the patient's optimal level of function has been targeted, the next step is to identify barriers that prevent the patient from achieving this optimal level. Both the rehabilitation therapist and patient work together via a thorough examination process to identify these barriers. Patient-reported measures of pain and function, as well as performance-based measures of function, should be used to identify the types of functional tasks that are problematic and to quantify the severity of these problems. Physical examination procedures are performed to identify the presence of physical impairments (i.e., muscle weakness, limited joint motion, joint stiffness, balance and coordination deficits) that may be associated with the functional problems. An assessment of the patient's living or work environments may be undertaken to identify environmental or social support factors that could be either potential barriers or potential assets in achieving optimal function. Assessment of biobehavioral characteristics (i.e., anxiety, fear, depression, self-efficacy) may also be helpful in determining whether any of these factors are influencing physical activity or responsiveness to rehabilitation interventions.

After specific barriers have been identified through the examination process, the rehabilitation therapist and patient design and implement a rehabilitation intervention program that addresses the specific barriers to optimal function. Rehabilitation interventions can be classified as either remedial or adaptive processes. Remedial rehabilitation works to *restore* or *establish* capacity or ability. It focuses on improving impairments in muscular strength and endurance, joint motion, cardiorespiratory fitness, balance and coordination, and cognitive function (depression, anxiety, fear, self-efficacy) and may also refer to retraining in lost skill sets, such as self-care, dexterity, or work skills. Adaptive rehabilitation works to *compensate* for lost or absent capacity or ability. It focuses on providing alternative or supplementary methods to perform a task or activity so that performance can be optimized. Adaptive rehabilitation includes the following methods:

- Providing equipment that substitutes for lost capacity
- Teaching new methods of performing tasks that incorporate existing capacity
- Altering the environment to facilitate performance
- Changing the requirements of the task

Most rehabilitation therapists use a combination of remedial and adaptive rehabilitation methods to achieve optimal function.

Rehabilitation is a multifactorial process that requires addressing a variety of features and issues to achieve the goal of obtaining optimal function and participation in life for patients with arthritis. Thus, it is logical that the rehabilitation process would require a multidisciplinary approach to achieve these goals. This chapter focuses its discussion mainly on the perspective of two rehabilitation disciplines, physical and occupational therapy. However, depending on the specific problems and needs of the individual patient, the services of other health care professionals, such as clinical psychologists, vocational rehabilitation counselors, rehabilitation engineers, or recreational therapists, should be used to provide the most comprehensive care for each patient. It should also be recognized that in many areas of the rehabilitation process, the roles and responsibilities of various disciplines overlap. For example, both physical and occupational therapists use methods to address a variety of impairments related to functional deficits. Both disciplines also use methods of functional retraining, education in joint protection techniques, and the use of assistive devices in their treatment programs. Because of the significant overlap in roles and responsibilities between disciplines, this chapter will not be discipline specific in the presentation of methods and issues related to the rehabilitation of people with arthritis.

REMEDIAL REHABILITATION APPROACHES

Pain control

Pain is a major cause of disability in people with arthritis. Physical modalities, including thermal agents and electrical stimulation, have been included in recommendations for the treatment of pain in people with arthritis.^{2,3} Thermal agents include hot or cold packs, paraffin, shortwave diathermy (SWD), ultrasound, and low-level laser modalities. Evidence for the use of these interventions to control pain is modest at present and supports selective rather than global use of these modalities. Low-level laser therapy has been shown to provide some relief of pain and stiffness in the foot, knee, and hand regions of patients with rheumatoid arthritis (RA) and also knee pain in patients with knee osteoarthritis (OA).^{4,5} Ultrasound used in water at 0.5 W/cm² demonstrated a small benefit in relief of hand pain in patients with RA but was not shown to be effective for relieving pain in patients with knee OA or in patients with back pain.⁵⁻⁷ Paraffin applied to the hand in combination with an exercise program seems to be helpful in reducing pain and stiffness and in improving range of motion in patients with RA and in those with scleroderma; however, the use of paraffin alone does not seem to be beneficial.^{8,9}

A recent randomized clinical trial compared the combined use of exercise with hot packs, hot packs and ultrasound, hot packs and SWD, or hot packs and transcutaneous electrical nerve stimulation (TENS) with exercise alone in women with knee OA.¹⁰ The researchers reported greater improvements in pain relief when exercise was combined with a thermal intervention than when the thermal agent was used alone. A recent systematic review of SWD for the management of knee OA also concluded that SWD can have an overall immediate effect on pain perception following completion of the last treatment session but that no long-term benefits are evident.¹¹ Additionally, the effects SWD are apparent only when it evokes at least some degree of thermal sensation.¹¹ Further studies (using comparable protocols and outcome measures) are needed to determine the possible long-term effects of thermal SWD in relieving pain in patients with arthritis.

TENS, the process of providing an electrical stimulus through the skin with surface electrodes for the purpose of reducing pain, has been shown to be effective in the treatment of pain. Use of TENS has been advocated as a stand-alone treatment of pain in published treatment guidelines for arthritis.^{2,3,5} There are many different applications of TENS that combine various stimulus parameters (pulse frequency, pulse duration, pulse amplitude) and various treatment durations. Low-frequency, high-amplitude TENS (sometimes referred to as acupuncture-like TENS) was shown to be effective in relieving hand and wrist pain in patients with RA, but higher-frequency TENS was not.¹² In patients with knee OA, high- and low-frequency TENS was deemed effective in increasing the pressure pain threshold after a single TENS treatment.¹³ However, patient-reported pain ratings at rest and during movement were similarly reduced by active TENS and placebo TENS, thus suggesting a strong placebo component of the effect of TENS.¹³ To this end, a recent systematic review of randomized or quasi-randomized controlled

trials could not confirm whether TENS is effective for pain relief in patients with knee OA.¹⁴

In summary, although thermal agents and TENS have a place in controlling pain in people with arthritis, their use should be limited to selective cases rather than global applications across all people with arthritis. When considering the rising cost of health care, many patients may be served better by instructing them in the home use of hot packs, warm baths, paraffin, or TENS for pain control rather than having them make frequent visits to a therapist to receive these treatments. An alternative to the use of physical agents for pain control is exercise and physical activity. A number of different types of exercise activity, including aerobics and strengthening exercises, may have a systemic effect on modulating pain. Studies have shown a reduction in pain thresholds in response to different types of pain stimuli at areas remote from the exercised limb segments, thus suggesting a centralized, systemic response.^{15,16} The use of various exercise applications for improving pain and function are addressed in subsequent sections of this chapter.

Range of motion

Loss of joint motion is a common impairment associated with arthritis. Limitations in joint motion or joint stiffness can increase the difficulty of performing activities of daily living (ADLs) and result in greater disability. It is also conceivable that with reduced joint motion, less joint surface area is available for distributing compression and shear loads across the joint surface. This could result in more concentrated loading in smaller areas of the joint surface and thereby lead to increased joint stress and potentially accelerate progression of the arthritis. Therefore, addressing limitations in joint motion is an important element of rehabilitation for people with arthritis. Published guidelines for the treatment of hip and knee OA recommend the use of treatments designed to maintain or improve joint mobility.² Such interventions may include stretching exercises (sometimes referred to as flexibility exercises), joint mobilization, and splinting to improve pain, function, and joint motion.

Stretching exercises are designed to increase the length of soft tissue structures that may be limiting joint motion, such as the joint capsule and musculotendinous units. Stretching exercises involve moving the joint to the end of the available range of motion and then applying some manual overpressure to increase passive tension in the target soft tissue structures. The stretch position should induce enough passive tension in the target structure to elicit a “slight stretch discomfort” but not to the extent that joint or soft tissue pain is elicited. This position is then held for a short period (Table 47.1).

In a study of 55 older adults with and without knee OA, three 60-second bouts of hamstring stretching with 60 seconds of rest between each bout resulted in immediate beneficial adaptations in terms of 4 to 5 degrees of increased knee extension range of motion.¹⁷ Similarly, in a small randomized trial of 19 female subjects between the ages of 65 and 89 years with limited ankle dorsiflexion, subjects who received an 8-week calf-stretching program

TABLE 47.1
Exercise prescription recommendations

Exercise	Intensity	Volume	Frequency
Flexibility	Stretch to the point of feeling tightness or slight discomfort	2-4 stretches/key muscle group; hold position for 10-30 sec A reasonable target is to perform 60 sec of total stretching time for each flexibility exercise	≥2-3 days/wk
Resistance			
Isometric	Low to moderate: 40%-60% MVC	1-10 submaximal contractions involving key muscle groups; hold the contraction for 1-6 sec	Daily
Isotonic	Low: 40% 1 RM	10-15 reps, 2-4 sets, 2- to 3-min rest intervals	2-3/wk
	Moderate: 40%-60% 1 RM	8-10 reps, 2-4 sets, 2- to 3-min rest intervals	
	High: >60% 1 RM	6-8 reps, 2-4 sets, 2- to 3-min rest intervals	
Aerobic	Low to moderate: 40%-60% of $\dot{V}O_2\text{max}$ /HRmax RPE: 12-14 = 60%-65% $\dot{V}O_2\text{max}$	Accumulation of 30-60 min/day Exercise may be performed in one (continuous) session per day or in multiple session lasting ≥10 min to accumulate the desired duration and volume of exercise per day	≥3 days/wk

MVC, maximal voluntary contraction (measurement of isometric strength); reps, repetitions; 1 RM, one rep maximum (measurement of isotonic or dynamic strength); RPE, rating of perceived exertion; HR max, age-predicted heart rate maximum; $\dot{V}O_2\text{max}$, maximal aerobic capacity (measurement of aerobic fitness).

Data from Garber CE, Blissmer B, Deschenes MR, et al. American College of Sports Medicine position stand. consisting of 10 repetitions of a 15-second hold at the end of the available range of ankle dorsiflexion had improved ankle dorsiflexion, higher agility test scores, and faster walking speeds than did control subjects.¹⁸ Although the most effective dosage for stretching may vary from muscle to muscle, it appears from these studies that improvements in muscle length and joint motion may be obtained from moderate-intensity stretching exercise. Patients who can hold for longer durations may not need to do as many repetitions. Likewise, if they cannot tolerate holding for longer periods, benefit may still be obtained by performing more repetitions at shorter durations.

Joint mobilization techniques are frequently used to increase joint motion by improving the accessory joint motions (i.e., sliding or distractions between joint surfaces) that accompany normal joint motion. For example, during knee flexion, the tibia slides posteriorly on the femur during the flexion motion of the joint. If this posterior sliding is inadequate, limited knee flexion motion will be present. The therapist performs joint mobilization techniques designed to restore the normal posterior slide, which in turn improves knee flexion motion. Joint mobilization techniques vary, depending on the joint motions being targeted and the accessory motions that accompany the targeted motions. Higher-intensity mobilizations (oscillations of the accessory motions near the end of the available range) are used to improve joint motion; however, lower-intensity mobilizations (oscillations of the accessory motions in the middle of the available range) can be used to induce relaxation and perhaps pain modulation.

Only a few studies have examined the effects of joint mobilization in patients with arthritis. In a randomized clinical trial of patients with knee OA, the combined use of joint mobilization with a supervised stretching and strengthening exercise program for all impaired lower extremity joints and the spine resulted in greater improvements in self-reported and performance-based measures of function than when only a home exercise program without joint mobilization was used.¹⁹ Changes in knee motion were not reported in this study. Similarly, in a randomized trial of patients with hip OA, subjects receiving a distraction joint manipulation technique, combined with lower extremity stretching and strengthening, had greater improvements in pain, self-reported hip function, hip range of motion, and walking speed than did subjects randomized to exercise without hip manipulation.²⁰ In these studies, groups randomized to exercise only did not appear to receive exercise programs equivalent to those of the groups undergoing the joint mobilization/manipulation techniques. Therefore, the exact contribution of these techniques to the outcomes is not clear. At any rate, combined use of joint mobilization techniques with other exercises appears to be helpful.³ Recently published systematic reviews further support the notion that the addition of manual mobilization to exercise therapy appears to be more effective in reducing pain than does strength training or exercise therapy alone in patients with knee OA²¹ and that joint mobilization may be an effective treatment option for those with hip OA in the short and long term.²²

Muscle strength

Muscle strengthening is recognized as an important element of rehabilitation for people with arthritis.^{2,3,12} Muscle weakness is frequently associated with greater disability in patients with arthritis, and in some cases, such as knee OA, there is debate whether muscle weakness may be a precursor to arthritis. In addition, muscles can play a significant role in absorbing and dissipating loads across joints, which may help reduce pain and prevent damage to joint structures. Muscle-strengthening programs have resulted in reduced pain, increased muscle force output, and improvements in performance-based and self-reported functional measures for some people with various forms of arthritis.^{2,12,23}

Several alternative types of strengthening exercises can be used. Isometric exercises involve contracting the muscle against resistance without allowing joint motion to occur. These types of exercises are usually performed at multiple angles throughout the joint's range of motion. Isotonic exercise involves moving a constant amount of resistance through a joint's range of motion. Weightlifting exercises are a type of isotonic exercise. In some clinic settings, computerized dynamometers can be used with isokinetic exercises to allow resisted muscle contractions to be performed through a range of motion at constant velocity. Few studies have compared the effectiveness of isometric, isotonic, and isokinetic exercise, but evidence suggests that all three types can improve pain, walking speed, muscle strength, and self-reported disability.²⁴

Strengthening exercises can be designed to use concentric or eccentric contractions. During concentric contractions the limb is accelerated against external resistance (e.g., gravity, weights), which results in overall

shortening of muscle length during the movement. During eccentric contractions the limb is decelerated against an external resistance, which results in overall lengthening of the muscle.

Functional activities involve combinations of isometric, isotonic, concentric, and eccentric muscle contractions. Therefore, a well-rounded strengthening program should include activities that involve each of these types of muscle contractions. Recently, some investigators have explored the use of functional task-specific strengthening in elderly subjects.^{25,26} With this type of training the therapist and patient identify which functional tasks are most problematic. The therapist then breaks the task up into segments that can be used as strengthening exercises. In this manner, patients train their weak muscles exactly as they will need to use them to perform tasks. As the patient gets stronger, the therapist adjusts how the patient performs the task-specific exercise, with more effort demanded from the target muscles as they get stronger. Some evidence suggests that this approach may be more effective than standard exercise approaches in improving overall function.^{25,26}

No matter what type of exercise is used in the strengthening program, adequate training dosage is an important consideration to obtain beneficial effects (see Table 47.1). The approach must provide enough loading on the muscle to induce a strength-training effect without exacerbating pain and inflammation of the joints. Recent studies indicate that using a graded progression of exercise resistance and adjusting training volume to match the level of resistance allow people with either fibromyalgia or RA to train intensely enough to obtain improvements in pain, strength, muscle hypertrophy, and performance-based and self-reported measures of function without exacerbating symptoms at their joints.^{27,28}

In many forms of arthritis, such as RA, the hands are particularly affected, with significant decreases in strength and range of motion secondary to the development of deformities. Therapy often focuses on remediating hand function by providing a home program of hand-specific resistive exercises, such as Thera-Putty, and full-range passive or active range-of-motion exercises. In a small nonrandomized study, 6 weeks of hand training resulted in a significant improvement in hand force and hand function in patients with RA, and the improvement was even more pronounced after 12 weeks.²⁹ A recent randomized trial of exercise therapy aimed at improving hand strength in individuals with hand deformities secondary to RA resulted in significant improvements in handgrip and pinch strength, as well as functionality.³⁰ Given the recent evidence that significant gains in hand strength in individuals with RA are most likely due to neural adaptations without gains in muscle mass, hand rehabilitation program for patients with RA should be designed to maximize this particular physiologic mechanism of strength gain.³¹

Aerobic capacity

Aerobic exercises are typically moderate-intensity exercises involving larger muscle groups that are performed over extended periods to improve cardiovascular function. Examples of aerobic exercise include walking, cycling, and pool exercises. Regardless of what type of exercise is used in the aerobic exercise program, maintaining an adequate aerobic dose of 40% to 60% of maximal aerobic capacity (maximum heart rate or $\text{VO}_{2\text{max}}$) is necessary (see Table 47.1). Aerobic exercise has been recommended as part of the management of patients with a variety of rheumatologic disorders in a number of published treatment guidelines.^{2,3,32,33} Aerobic exercise programs have been shown to reduce pain, improve function and quality of life, increase aerobic capacity and endurance, and improve mental health.^{2,33-35}

Walking programs have generally been studied for effectiveness. The Ottawa Panel recently concluded that aerobic walking combined with stretching and strengthening exercises, education, or behavioral programs is recommended to improve pain relief, functional status, and the quality of life of adult individuals with OA.³² Cycling is another form of aerobic exercise that can be beneficial. Low-intensity cycling was shown to be as effective as high-intensity cycling in improving function and gait, decreasing pain, and increasing aerobic capacity in subjects with knee OA.³⁶ Cycling should be considered for those with arthritis who may have difficulty with a walking program because of joint pain.

Aquatic exercise programs are an alternative for people with rheumatologic conditions because the buoyancy of water helps reduce loading on joints and thus makes it easier for patients with arthritis or fibromyalgia to exercise. These programs can include a combination of limb movements against water resistance and walking or jogging in the pool. Several studies of aquatic programs have reported improvements in pain, muscle strength, aerobic capacity, self-report and performance-based measures of function, daytime fatigue, anxiety, and depression.^{34,35,37}

Balance and agility

In recent years, more attention has been directed to the importance of balance in patients with arthritis. Studies have indicated that people with knee OA have deficits in measures of balance when compared with age- and gender-matched controls and that these balance deficits may be associated with limitations in function and functional decline.³⁸ In some cases, balance may be altered even in the absence of deficits in muscular strength.³⁹ Therefore, rehabilitation programs may need to incorporate interventions specifically designed to challenge balance ability in people with arthritis.

A variety of activities can be used for balance training in people with arthritis. Some authors have described techniques that use a combination of balance board and roller board activities.⁴⁰ Single-leg standing and tandem standing activities, as well as agility-training techniques that focus on quick stops and starts, sudden changes in direction, and crossover stepping, have also been combined with balance board activities to challenge balance.⁴⁰ Tai chi activities are also being used more frequently in aging people and those with arthritis.⁴¹ Even though strengthening exercise can result in improved balance and function, some evidence indicates that balance- and agility-training techniques, when combined with strengthening exercises, can result in greater short-term improvements in functional measures than strengthening alone can.⁴²

Pain-related fear

Patients' perception that physical activity or exercise may harm their joints is sometimes referred to as "pain-related fear." Pain-related fear may be a barrier to optimal patient participation in an exercise or physical activity program. Pain-related fear has been shown to be associated with poorer physical function scores in people with arthritis.⁴³ One rehabilitation approach that may improve the outcome of rehabilitation in patients with pain-related fear is "graded *in vivo* exposure" (GivE).⁴⁴ In this approach the therapist and patient identify the types of physical activity or tasks that invoke a fear response and then rank-order the tasks with respect to the amount of fear. At the beginning of therapy, patients are educated in the concept of fear avoidance behavior and how this can limit an individual's ability to function. During therapy the therapist models task-specific modifications and proper body mechanics for the fear-inducing tasks or activities. The patient then practices these modifications and body mechanic techniques under supervision of the therapist. The gradual and systematic exposure to the fear-inducing activity is intended to disconfirm the patient's pain and fear-related expectations associated with the physical activity.

Although the GivE approach has not been formally evaluated in people with arthritis, it would seem that this type of approach could be helpful for patients with arthritis who have fear of performing certain physical tasks or activities. Clinicians should assess whether their patients with arthritis are experiencing pain- or activity-related fear and pursue approaches that will help diminish the fear so that functional capacity can be optimized.

ADAPTIVE REHABILITATION APPROACHES

Because many arthritic conditions are progressive in nature, teaching compensatory skills to promote independent, safe, and comfortable functioning is a key rehabilitation technique. Many people with arthritis experience limitations in their ability to perform ADLs because of limitations in range of motion, strength, and endurance. The phrase *activities of daily living* refers to a very large category of tasks and activities: those that involve taking care of oneself and one's immediate environment. They are often broken down into basic ADLs, or tasks related to self-maintenance, such as functional mobility (including transfers), personal hygiene and grooming, bathing, bowel and bladder management and hygiene, dressing, eating, and sexual activity, and instrumental ADLs, or tasks that involve interacting with the immediate environment, such as care of others, use of communication devices, community mobility, financial management, meal preparation, home care, response to emergencies, and shopping.⁴⁵ Strong associations have been made between ADL ability and impairments in strength, range of motion, and endurance, which suggests that remediating these impairments can improve performance of ADLs.⁴⁶ However, research also suggests that a person's level of impairment does not always predict ADL performance⁴⁷ because other factors, such as the environment or pain-related fear, can facilitate or prevent function. Providing compensatory techniques is one method to improve ADL ability and the most responsive to changes in ability as the disease progresses.

Assistive devices

One method to remediate ADLs is to provide an assistive device. "Assistive device" is a broad term defined as "any item, piece of equipment, or product system, whether acquired commercially off the shelf, modified or customized, that is used to increase, maintain, or improve functional capabilities of individuals with disabilities."⁴⁸ Even though prescription of assistive devices is common in therapy, only limited high-quality evidence is available to support their use. The research available suggests that assistive devices can improve performance in people with arthritis⁴⁹ and that they have been associated with improved psychological well-being.⁵⁰

Unfortunately, compliance with the use of assistive devices may be limited; estimations suggest that 36% of bathing equipment, 26% of dressing devices, and 19% of mobility devices are not used.⁵¹ Compliance depends on a variety of factors such as age, diagnosis, disease severity, and perception of the utility and attractiveness of the assistive device.⁵² The environment in which the device will be used affects compliance; for example, durable medical equipment, such as toilet seats, may be discarded if they do not fit the toilet, if the user cannot access the bathroom because of narrow doorways, or if they do not fit the person.⁵¹ One way to increase compliance is to ensure that assistive devices are prescribed by an experienced person and that patients are properly trained in their use.⁵¹

One type of assistive device that can be either remedial or compensatory is a hand orthotic device, or splint.³ Hand splints can be used for a variety of reasons—to provide support, align joints, immobilize joints, reduce pain, prevent or correct deformity, assist weak muscles, or position the hand for functional activities—and they are particularly useful for patients with RA and carpometacarpal (CMC) joint OA. Hand splints can be custom-made by an occupational therapist or be purchased prefabricated.

Although hand splints are frequently provided to patients with arthritis, few high-quality studies have been performed to assess their effectiveness. Systematic reviews of the effectiveness of splints for RA have reported that the evidence is unclear whether splints significantly improve work performance, although they may have a positive effect on pain.⁵³ A systematic review of the effectiveness of opponens-type splints (a splint that immobilizes the thumb) in the treatment of CMC joint OA reported that these splints are effective in both reducing pain and increasing function.⁵⁴ One study that examined the effectiveness of splinting on increasing range of motion of the proximal interphalangeal joints of individuals with RA reported that both static splints (i.e., splints that have no moving parts) and dynamic splints (i.e., splints that apply a graded or increasing force on a contracted joint) are effective in increasing range of motion, increasing hand strength, and improving function.⁵⁵ Although the evidence to support hand splints is somewhat equivocal, Egan and colleagues⁵⁶ suggested that since splints are relatively inexpensive and not harmful, current clinical practice should be to prescribe splints for patients on a case-by-case basis to see whether they help.

Lower extremity orthoses, such as knee braces and shoe inserts, can also be used as adjunctive interventions to reduce pain, relieve joint stress, or improve joint stability in people with arthritis. Knee orthoses have specially designed axes and straps to reduce compartmental loading of the knee. The most common type is a valgus brace, in which a valgus force is applied to the knee through the brace to unload the medial compartment. These types of braces can also be modified to apply a varus load to the knee for patients with lateral compartment involvement. Evidence of the effectiveness of these braces is limited, but it appears that they can help some individuals.⁵⁷ Biomechanical studies have shown that these braces can reduce joint compartmental loading,⁵⁸ and a recent study suggested that bracing may improve joint stability.⁵⁹ Currently, no specific guidelines are available to identify who will respond to this type of bracing. There is probably a cutoff point with regard to the degree of joint deformity beyond which the brace may no longer be effective, but this cutoff point has not yet been established. The willingness of a patient to wear the brace can also be a limiting factor inasmuch as some patients find the brace to be cumbersome. However, newer, lighter-weight designs may help address this problem. Valgus bracing may be a reasonable option for patients who are not good candidates for surgical realignment procedures.

Like knee braces, shoe inserts may also be used to reduce lower extremity pain or joint stress. A lateral wedge insert is believed to reduce medial compartment loading indirectly by enhancing foot and ankle pronation, which in turn should result in increased valgus load at the knee. Some biomechanical studies have indicated that these inserts can reduce varus moments at the knee.⁶⁰ The use of a "subtalar" strap, combined with a lateral wedge, seems to have a moderately better effect in reducing medial compartment loads, as well as in improving pain and function, than a lateral wedge alone does.^{61,62} The strapping may help by preventing excessive

pronation at the foot and ankle, which might otherwise dissipate the effect of the insert on the knee. Regardless of whether a subtalar strap is used, it appears that this intervention is most effective in patients with mild to moderate arthritis and may not be very effective in those with severe knee OA. Additionally, recent evidence suggests that laterally wedged insoles provide no long-term symptomatic or structural benefits for patients with knee OA.⁶³

Self-management instruction

One common trend in arthritis management is education in self-management techniques.^{2,3} These programs provide people with arthritis education about aspects of their disease, such as pain management, fitness and exercise, and healthy eating, and are often combined with training in effective coping, such as goal setting, action plans, and problem solving.^{64,65} Such programs can vary tremendously in content and can include disease information, methods of pain management, exercise, training in ADLs, social skills training, and relaxation techniques.⁶⁴ Although the quality of the research varies, studies have generally found that education programs have a small effect on pain and a moderate effect on function in the short term,⁵³ but carryover of these positive outcomes is less apparent.^{65,66} Self-management programs using a variety of session numbers,⁶⁴ group versus individual design,⁶⁷ and various delivery systems such as a mail delivery program⁶⁸ or the Internet⁶⁹ have been shown to be effective. One common educational program is joint protection (JP). JP techniques are taught primarily to those with RA, although patients with OA have also been trained in JP.⁷⁰ JP programs focus on teaching techniques thought to reduce stress on joints weakened by the disease, thereby reducing the tendency for deformities such as subluxation and ulnar drift. Several high-quality systematic reviews and clinical practice guidelines specifically support the effectiveness of JP techniques in improving function.^{3,53}

Fatigue

Chronic fatigue is a very common, yet frequently undertreated symptom of many types of arthritis. Chronic fatigue in those with arthritis has been described as being different from the normal tiredness experienced by healthy people. Chronic fatigue is characterized as a profound lack of energy that is not linked to specific overexertion but occurs almost randomly.⁷¹ Chronic fatigue is reported by patients with arthritis to significantly affect many aspects of their life, including basic ADLs, work and leisure, and family relationships. Fatigue is reported to limit social contact, and many workers cut their work back because of fatigue.^{72,73} Although fatigue is often identified to be as limiting as pain for many people with arthritis, they seldom discuss it with others.

Interventions to remediate fatigue can generally be divided into two types: aerobic exercise and behavioral interventions. Aerobic exercise has been shown to be an effective method of reducing fatigue, and research suggests that low-intensity aerobics (such as brisk walking) performed at least three times weekly for 15 to 30 minutes can reduce feelings of chronic fatigue.⁷¹ Behavioral programs that provide education in self-management techniques have been shown to be effective in reducing fatigue.⁷¹ One fatigue self-management program is energy conservation. Energy conservation provides persons with arthritis specific strategies to address issues related to fatigue, such as valuing rest, budgeting and banking energy, taking planned rest periods, breaking fatiguing tasks down into smaller components, using good body mechanics, and learning to communicate personal needs to others.⁷⁴

Work adaptations

Work is a valued activity, both for individuals and for society. Arthritis is the third leading cause of work disability: 8.2 million working U.S. adults (about 1 in 20) report work limitations as a result of arthritis.⁷⁵ Work disability refers to limitations in the ability to work because of impaired health and is manifested as premature work cessation (before the normal age of retirement) and, among employed persons, as reduced productivity.

People with RA have identified several job accommodation strategies that reduce work disability. One common accommodation was to make the job more flexible, including controlling work hours, taking rest breaks, or delegating tasks. However, Chorus and coauthors⁷⁶ reported that job modifications that resulted in loss of productivity, such as working fewer hours or delegating, were associated with a greater risk for eventual work disability. Modifications developed with the assistance of a health care provider, such as work-specific self-management programs and ergonomic assessments to modify the work environment or work task methods to better fit the needs

of workers with arthritis, have been reported to be effective ways to adapt the job.⁷⁷⁻⁷⁹ Workers who received work interventions by health care professionals were less likely to report work disability.⁷⁸

One method for obtaining work modifications is use of the Americans with Disability Act (ADA), Title I. The ADA was enacted in 1990 to prevent discrimination in the workplace against workers with disabilities. An important aspect of the ADA was to ensure that employers provide workers with any requested “reasonable accommodation,” or a modification or adjustment in a job or work environment that enables a qualified person with a disability to perform essential job tasks. Reasonable accommodations can include physical changes in the environment (e.g., raising or lowering work heights), adaptive equipment (e.g., special chairs, power-assisted lifting devices), and changes in work organization (e.g., telecommuting, altered hours, changes in nonessential job function). Although the ADA is available for people with arthritis, few use it to remain employed. A recent study reported that although 63% of workers with arthritis needed a job accommodation, only 10% had used the ADA. Factors that affected use of the ADA included not knowing that the ADA was available, the perception that they did not have a disability that could be addressed through the ADA, lack of skill in requesting reasonable accommodations, and no interaction with a health professional who suggested using the ADA.⁸⁰

Vocational rehabilitation is another method to prevent work disability. Vocational rehabilitation is a coordinated, multidisciplinary program that addresses work retention, prevention of loss of work, or return-to-work programs. Vocational rehabilitation assists people in reentering employment in the same or different jobs after a period of sick or disability leave. The actual interventions vary according to the needs of each patient and are developed on a case-by-case basis. The effectiveness of vocational rehabilitation for people with arthritis has been assessed, with conflicting results. A systematic review of six uncontrolled studies on vocational rehabilitation for people with arthritis reported some evidence of short-term improvement in employment.⁸¹ More recent controlled studies were equivocal: Allaire and coworkers⁸² reported that vocational rehabilitation had a positive effect on job loss, whereas de Buck and associates⁸³ reported no difference when compared with usual outpatient care.

Unfortunately, work disability is rarely addressed in those with arthritis. A recent qualitative study examining issues experienced by workers with arthritis suggested that work is rarely discussed with physicians or health care practitioners.⁷⁸ Studies on workers with arthritis find that they frequently implement coping strategies such as changing jobs, reducing hours, or reconfiguring their workstation, but they rarely have interventions by health care practitioners.⁷⁸ Those in these studies who report having had work interventions by health care professionals were more likely to report less work disability.

Although ergonomic assessment, work self-management, and vocational rehabilitation may be effective strategies to reduce work disability, most workers with arthritis do not obtain these interventions. They may not know that ergonomic assessments exist, they may not know whom to request or pay for an ergonomic assessment, and they may fear disclosing their condition to an employer.⁷⁸ Unwillingness to disclose their arthritis condition to an employer and coworkers is fairly common in workers with RA. Many workers with RA report that they fear adverse consequences, such as loss of work, discrimination in job promotions, being less valued as a worker, stigmatization, and dealing with negative coworker reactions.⁷⁸ In addition to the barriers to obtaining ergonomic assessment and intervention through work, many workers with RA do not discuss their problems at work with their rheumatologists, who are gatekeepers for these interventions.⁸⁴

SUMMARY

The purpose of rehabilitation is to assist patients with arthritis in restoring and maintaining an optimal level of function. The patient is the main stakeholder in this endeavor and therefore sets the bar in determining the optimal level of function. Rehabilitation therapists identify the barriers that may limit the ability of people with arthritis to achieve optimal function and then provide interventions to overcome these barriers. Because the barriers are often multifactorial, a successful rehabilitation process will require a multidisciplinary effort that involves not only physical and occupational therapists but also clinical psychologists, vocational rehabilitation counselors, rehabilitation engineers, and recreational therapists.

In this chapter both remedial and adaptive rehabilitation approaches were discussed (Table 47.2). Many patients with arthritis need a combination of both approaches. Remedial rehabilitation is directed at restoring or

TABLE 47.2

Summary of rehabilitation techniques

Intervention	Application	Comments
Remedial approaches		
Physical agents Thermal agents (e.g., heat, cold, ultrasound) Electrical stimulation (e.g., TENS)	Pain control	Most appropriately applied on a case-by-case basis
Stretching/range of motion	Improve joint motion Improve function	
Joint mobilization	Improve joint motion Pain control Improve function	Lower-intensity joint mobilization may be effective in controlling pain.
Strengthening exercise Isometric Isotonic Isokinetic "Task specific"	Increase muscle force output Pain control (when combined with physical agents) Improve balance Improve function	Patients need a combination of strengthening (isometric, concentric, etc.) to best improve functional ability.
Aerobic exercise	Improve aerobic capacity and endurance Pain control Reduce fatigue Improve function Improve mental health	Walking or cycling programs have been shown to be effective methods to improve aerobic fitness.
Balance training	Improve balance and agility Improve function	Tai chi programs are potentially effective methods to improve balance.
Adaptive approaches		
Assistive devices	Compensate for impairments Improve function Improve mental health	Compliance can be an issue if the devices are improperly prescribed or provided without training in their use.
Splinting	Pain control Improve joint motion Provide support Immobilize joints Correct deformity Assist weak muscles Improve function	Splints should be considered on a case-by-case basis.
Educational programs Self-management Joint protection Vocational rehabilitation	Pain control Improve function Reduce fatigue	

TENS, transcutaneous electrical nerve stimulation.

establishing physical capacity and ability, with a focus on addressing the impairments associated with arthritis.

Adaptive rehabilitation is directed at finding ways to compensate for lost or absent physical capacity or ability and focuses on developing alternative or supplementary methods to assist patients in improving their performance

of tasks. Because many people with arthritis are still of working age, ergonomic assessments and work task modifications for these patients are important. Physicians and therapists may need to take a more proactive role in making sure that the occupational needs of their patients with arthritis are being assessed and addressed.

Complementary and alternative medicine

■ BRIAN BERMAN ■ GEORGE LEWITH ■ ERIC MANHEIMER ■ FELICITY L. BISHOP ■ CHRIS D'ADAMO

- The majority of rheumatology patients use some form of complementary and alternative medicine (CAM).
- Acupuncture, herbal medicine, nutraceuticals, and homeopathy are among the most commonly used CAM treatments.
- The majority of research on traditional Chinese medicine in the West has focused on acupuncture.
- Studies have shown acupuncture to be effective for specific types of pain reduction.
- Some herbal therapies may be as effective as analgesics and antiinflammatories for rheumatic and musculoskeletal conditions.
- Nutraceuticals, in particular glucosamine and chondroitin, may be effective in the treatment of osteoarthritis and in prevention of long-term joint damage.
- Homeopathy has not been definitively proven to work for treatment of rheumatologic conditions.
- Physicians should consider that CAM can be integrated into the conventional management of rheumatologic conditions in a thoughtful, professional, and cooperative manner.
- Rheumatologists need to consider the view of patients with rheumatic diseases and be prepared to have informed discussions with them about CAM.

OVERVIEW

Complementary, alternative, and integrative medicine are blanket terms that comprise a large variety of health treatments clustered together because they are generally considered to be outside the parameters of conventional treatment.¹ The terms *complementary, alternative, and integrative* refer not just to the particular modalities used but to the manner in which health care is obtained; in other words, people can obtain health care from a nonconventional practitioner in conjunction with conventional care (complementary) or instead of conventional care (alternative), or from a provider or group of providers that have blended conventional and nonconventional care in their practice (integrative).

It is commonly known that the traditional medical systems of Asia have been practiced for thousands of years, but the history of complementary and alternative medicine (CAM) in the West, although well documented,² is not always discussed. CAM use in the West is not a recent phenomenon; rather, many of the alternative systems of medicine being used today (e.g., herbalism, chiropractic, naturopathy, and homeopathy) have evolved alongside allopathic medicine. In addition, Asian systems of medicine were formally introduced to the West as early as 1683, when the first European text on acupuncture and arthritis was written,³ and the first journal articles on acupuncture appeared in the 1820s.^{4,5} Over time, as these medical systems developed and the needs of the population continuously changed, the popularity of CAM ebbed and flowed accordingly.⁶

WHO SEEKS COMPLEMENTARY AND ALTERNATIVE MEDICINE AND WHY

According to nationwide population-based surveys, a substantial proportion of U.S. adults use CAM,⁷ and the prevalence of CAM use has remained

consistently high in recent years.⁸ CAM use is more prevalent among women, the middle aged, and the well educated⁹ but is by no means restricted to these groups.^{10,11}

People who have chronic diseases in general and rheumatologic diseases in particular are more likely to use CAM. Reported prevalence rates for CAM use in rheumatology patients vary across surveys and diagnoses.¹¹⁻²⁰ CAM is also commonly used by rheumatology patients in non-Western cultures.²¹⁻²⁴ Variation in reported prevalence rates probably reflects differences in methodology and CAM definitions as well as differences in underlying rates of CAM use.

Rheumatology patients use CAM partly because they perceive a need for additional treatment. Health indicators that have been associated with CAM use in arthritis, lupus, and/or osteoporosis include more severe pain, poorer functional status, poorer self-rated health, longer disease duration, and worse lumbar spine T-score.^{11,15,18,19,23,25-27} Consistent with these findings, rheumatology patients commonly report using CAM to help them manage ongoing symptoms such as pain and fatigue.^{23,25,28} Having additional comorbidities may also increase the likelihood of CAM use.^{11,27,29} Personality factors have also been associated with CAM use.^{29,30}

CAM is often used alongside rather than instead of conventional medicine,^{13,22,27,31-33} and patients make decisions about individual CAM modalities in the context of other treatments that they are currently using.³⁴ When patients take an active role in choosing to try CAM treatments they also review their choices and cease using therapies that prove ineffective³⁵ or otherwise dissatisfying.³⁶ For some patients, CAM provides a means to actively avoid or delay more invasive conventional treatments such as surgery.³⁷ For others, CAM is simply another form of treatment that they will try if their doctor recommends it.³⁸

CAM use can be seen contextually as just one part of patients' attempts to cope with the challenges of illness on a day-to-day basis. From this perspective, the task for doctors is to support and guide patients in making safe, well-informed decisions about their personal use of CAM in relation to other forms of health care. Evidence strongly suggests that patients would value such support and guidance, particular with regard to potential drug interactions.¹⁶

WIDELY USED COMPLEMENTARY AND ALTERNATIVE MEDICINE SYSTEMS AND THEIR THERAPIES

Surveys indicate that chiropractic, copper bracelets, magnets, herbs, topical treatments, electrical stimulators, nutraceuticals, homeopathy, massage, acupuncture, diet therapies, relaxation, and spiritual healing are all therapies used by rheumatology patients.^{39,40} This section aims to give a brief introduction to the philosophy and practice of a few main, commonly used modalities. These examples have been chosen to illustrate the complexity of CAM systems as well as to introduce the reader to some of the major clinical, philosophical, and research issues that must be confronted if integration of these therapies into mainstream medical practice is to occur.

Traditional Chinese medicine and acupuncture
Philosophy and history

Traditional Chinese medicine (TCM) is the product of thousands of years of philosophical, political, spiritual, and scientific evolution. Although its exact origin remains controversial, it is generally accepted that the first true Chinese medical texts emerged around 200 BC.⁴¹ TCM is an intricate medical system based on ancient philosophies, symptom-based clinical practice, a complicated individualized diagnostic system, and a variety of treatment

modalities including various types of acupuncture, massage (*tui na*), and herbal medicines. Like many CAM systems, TCM is based on a belief in the existence of a life force or vital energy that runs through the body and affects its functioning. Imbalances are diagnosed into syndrome patterns according to a number of complex yet subtle theories that provide the basis for treatment. Central to this is the theory of yin and yang. The terms and concepts within TCM have no Western equivalents; at best, they are roughly translated and are therefore easily misinterpreted.

Treatment

The TCM system encompasses many different treatment modalities, each, according to traditional theories, used to shift the vital energy of the body. Many of these techniques stimulate specific points on the body to alter the flow of *qi* (a term frequently used to describe the life force or energy in the body); usually, these points are located on meridians (specific channels that carry *qi* though the body; Fig. 48A.1). Acupuncture involves the insertion of thin, stainless steel needles into these points. Internal remedies are a vital component of TCM. These herbal remedies are always given in combination and are chosen to complement and balance each other. Additionally, TCM incorporates a unique system of massage called *tui na* and uses meditative exercises such as *qi gong*.

The TCM approach to rheumatic disease is very different from that of conventional modern medicine. The concept of rheumatic disease as it is understood in the West does not exist in TCM. The TCM treatment of rheumatic disorders, as in many CAM disciplines, is individualized, and the majority of rheumatic disorders fall into the general classification of painful obstructions (*bi syndrome*). Consequently patients with the same conventional diagnosis may receive different TCM diagnoses and treatments.

Evidence

Although there have been many randomized controlled trials examining the use of acupuncture for treatment of rheumatic conditions, they have often been of questionable methodologic quality. As a result, systematic reviews are of limited value and difficult to interpret. For example, for the rheumatic conditions of fibromyalgia⁴²⁻⁴⁴ and rheumatoid arthritis,^{45,46} no firm conclusions about efficacy, or lack thereof, can be drawn from systematic reviews because the existing randomized controlled trials are scarce, underpowered, heterogeneous, and often methodologically unsound.

However, for musculoskeletal pain (i.e., back and neck pain) and osteoarthritis, there is a substantial database of adequately powered and methodologically sound randomized controlled trials, which provide a reliable evidence base for systematic reviews. Although there have been previous summary-data systematic reviews of the use of acupuncture for musculoskeletal pain and osteoarthritis, the most current and valid estimates of the effects of acupuncture for treatment of these two conditions comes from a 2012 meta-analysis of individual patient data.⁴⁷ The individual patient data for acupuncture included data for individual participants in 29 trials, totaling 17,922 patients. Each trial was reanalyzed using analysis of covariance, with the standardized mean difference (i.e., post-treatment scores divided by pooled standard deviations) as the dependent variable, and the covariates being the baseline scores and the variables used to stratify randomization. The standardized mean difference was the measure of effect size because the trials assessed the same pain outcome but measured pain in various ways. The meta-analysis found statistically significant differences between true acupuncture and a sham acupuncture control procedure, and also between true acupuncture and no acupuncture. After exclusion of a set of outlier

Fig. 48A.1 Qi is believed to run through the body in channels called *meridians*. Although most meridians are associated with a major organ of the body (e.g., kidney, spleen), they each govern a much broader range of emotional and physiologic functions. Although they flow inside the tissue and organs of the body, the meridians are accessible from the surface in some areas; thus the *qi* can be manipulated by needling acupuncture points on the meridians. However, *qi* flow is not restricted to specific channels; there are numerous acupuncture points that are not located on meridians.

trials that strongly favored acupuncture, the effect sizes were fairly similar for these two rheumatic conditions. Relative to a sham acupuncture control group, participants receiving true acupuncture had less pain, with effect sizes of 0.23 (95% confidence interval [CI], 0.13 to 0.33) and 0.16 (95% CI, 0.07 to 0.25) for musculoskeletal pain and osteoarthritis, respectively; the corresponding effect sizes were 0.55 (95% CI, 0.51 to 0.58) and 0.57 (95% CI, 0.50 to 0.64) relative to a no-acupuncture control group. The average effects of acupuncture relative to no acupuncture were thus of clear clinical relevance. The effects of acupuncture relative to sham acupuncture were smaller; however, there were nonetheless robust differences that could be clearly distinguished from bias.

The relatively modest effect sizes for acupuncture relative to a sham acupuncture procedure and the larger effects of acupuncture relative to a no-acupuncture control condition suggest that other factors besides the point-specific placement of the needles play an important role in the overall therapeutic effect of acupuncture. These factors include the nonspecific physiologic effects of needling as well as the psychological effects related to the participants' expectations and beliefs that acupuncture will be more effective than no acupuncture (i.e., the placebo effects). This individual patient data meta-analysis of acupuncture studies has provided the strongest evidence to date that acupuncture is a reasonable referral option for patients of rheumatologists.^{48,49}

In addition to the effectiveness of acupuncture, other important considerations in determining whether or not to include acupuncture as part of standard care for rheumatology patients include acupuncture's adverse effects and its benefits relative to its costs. Incidence rates for major adverse effects of acupuncture, which are extremely rare, are best estimated from large prospective surveys of practitioners. Four such surveys of acupuncture safety, two conducted in Germany^{48,49} and two in the United Kingdom,^{50,51} confirm that serious adverse events after acupuncture are very uncommon.

It is also important to study the benefits of acupuncture relative to its costs, using cost-effectiveness trials.^{48,52,53} Indeed, because acupuncture has a low risk of adverse events, and because rheumatology patients are accepting of acupuncture,⁵⁴ its benefit-cost ratio is probably the most important factor to consider in determining acupuncture's clinical usefulness. Five methodologically sound trials have evaluated the cost effectiveness of acupuncture for rheumatic conditions, including two trials in patients with low back pain,^{52,55} two in patients with osteoarthritis,^{33,56} and one in patients with neck pain.⁵⁷ The outcome measure used in all of these trials was the incremental cost incurred per quality-adjusted life-year gained. All of these trials found that acupuncture treatment was associated with significantly higher costs than usual care, with this increase in costs due mostly to the cost of the acupuncture treatments. However, these trials also all found that acupuncture provided a cost-effective use of health care resources. That is, in all five of these cost-effectiveness trials, the incremental cost-effectiveness ratio per quality-adjusted life-year gained met international threshold values for a cost-effective treatment.

Several systematically derived evidence-based clinical practice guidelines exist for both osteoarthritis and low back pain. Major clinical practice guidelines for osteoarthritis have not endorsed the use of acupuncture for this condition, primarily citing the fact that there is not sufficient conclusive evidence of clinical efficacy or cost effectiveness to allow a firm recommendation.⁵⁸⁻⁶¹ However, these guidelines are periodically updated, and their recommendations can change with changes in the evidence landscape. In contrast, major guidelines for treatment of low back pain⁶²⁻⁶⁵ generally recommend that clinicians consider acupuncture as one possible treatment option for patients with low back pain. Indeed, because the UK National Institute for Health and Clinical Excellence recommended acupuncture as a treatment option for patients with low back pain,⁶² the UK National Health Service now provides a maximum of 10 sessions of acupuncture over a period of 12 weeks for people with low back pain that has persisted for longer than 6 weeks.

Herbal medicine

Philosophy and history

Herbs are the most popular and ancient CAM modality⁷ and are commonly used in isolation with expectations that they will treat a particular disease or symptom. Traditionally, combinations of herbs are used in multiple organ systems and are applicable to many different conditions. Herbal treatment protocols are highly individualized, and indications for herbs may be very specific. The majority of herb users self-medicate without informing their doctors⁶⁶ or herbalist, and inappropriate selection or combinations of herbs can cause adverse events that may mimic, magnify, or oppose the effects of pharmaceuticals^{66,67} (Table 48A.1). Accordingly, inappropriate combinations or improper use of herbs can result in serious adverse effects. One such

example involves ephedra,⁶⁸ a powerful sympathetic nervous system stimulant that when used in excessive doses or inappropriate situations for weight loss and increased energy has resulted in serious adverse effects.

The pragmatic clinical practice of traditional herbalism is a plant-centered whole system and requires the use of whole plant material as it is found naturally. This ensures that all the possible complex and unidentified synergistic compounds within the plant are included along with the known active constituents.

Treatment

Herbs are usually prescribed in combination and treatment is individualized. Treatments are usually given orally but may be prescribed as external salves. The bulk of a typical herbal formula is composed of various different herbal actives, including antirheumatics and antiinflammatories such as sarsaparilla, black cohosh, celery, meadowsweet, nettle, turmeric, boswellia, wild yam, devil's claw, and ginger. Often, blends contain diuretics, immune stimulants, circulatory stimulants, and digestive tonics as well; only a small portion of the blend addresses symptoms through analgesic action.⁶⁹ Nutritional approaches are frequently combined with herbal approaches; ideally, herbs are woven into the daily diet as spices and foods.

Evidence

To date, systematic and meta-analytic reviews of the literature in rheumatology indicate that a number of herbs may be effective treatments for rheumatic and musculoskeletal conditions.⁷⁰⁻⁷³ These herbs have been evaluated as individual products, in contrast with their traditional use. Those for which there is the strongest clinical evidence to date are capsaicin, devil's claw, ginger, boswellia, and several herbal combination products (Phytodolor, SK1 306X).

Capsaicin

Capsaicin is an extract of chili peppers from the genus *Capsicum*, which includes the cayenne pepper commonly used in culinary applications. When used therapeutically for pain relief, capsaicin is usually applied topically as a gel with a capsaicin concentration ranging from 2.5% to 8%. The primary mechanism through which capsaicin is thought to reduce pain is depletion of substance P, a neuropeptide involved in the transmission of pain signals from nerve endings to the brain and the activation of inflammatory cytokines in joints. Many high-quality randomized, double-blind, placebo-controlled trials have found topical application of capsaicin gel to be an effective treatment for osteoarthritis pain. Four randomized controlled trials investigated topical capsaicin (cayenne) for the treatment of osteoarthritis.⁷⁴⁻⁷⁷ Collectively, meta-analysis of these data indicates that capsaicin is an effective therapy for pain, tenderness, and impaired range of motion.^{73,78} Pooled data in a meta-analysis conducted by Zhang and Li Wan Po⁷⁸ found that topical application of capsaicin in concentrations between 2.5% to 7.5% was four times as effective as placebo gel in reducing pain and tenderness of osteoarthritis. No serious adverse effects were noted in these trials, although minor burning following application of capsaicin gel at these concentrations is relatively common. Motivated by the relatively frequent sensation of minor burning experienced at these concentrations, a recent trial conducted by Kosuwon and colleagues⁷⁹ assessed topical application of capsaicin at a concentration of 1.25% in 100 patients with mild to moderate osteoarthritis of the knee. The authors determined that capsaicin at this lower concentration was effective in improving pain, stiffness, and function. Although a mild burning sensation was common, no participants dropped out of the study for this reason. Thus lower concentrations of topically applied capsaicin appear to be an effective treatment option for mild to moderate osteoarthritis.

Devil's claw

Devil's claw is an extract obtained from the root of the African plant *Harpagophytum procumbens*. Devil's claw has been found to have strong antiinflammatory and analgesic effects,⁸⁰ thought to be due largely to high concentrations of the iridoid glycosides, including harpagoside. Numerous observational studies and several high-quality randomized, placebo-controlled trials and systematic reviews have been conducted assessing the efficacy of devil's claw in osteoarthritis. Brien and associates⁸¹ reviewed 14 studies examining devil's claw as a treatment for osteoarthritis: 4 double-blind, placebo-controlled trials, 2 comparator trials, and 8 observational studies. The authors concluded that devil's claw appears to be effective in reducing the pain of osteoarthritis, although higher-quality trials are needed. Gagnier and colleagues⁸² reviewed six randomized trials and determined that devil's claw standardized to 60 mg harpagoside was a moderately effective treatment for osteoarthritis of the spine, hip, and knee. Although devil's claw appears to carry only a minor risk of adverse effects compared with

TABLE 48A.1
Reported potential herb-drug interactions relevant to rheumatology practice

Herb	Pharmaceutical	Effect	Mechanism/comment
Asian herbal mixtures: Sho-saiko-to	Prednisone	Decreased AUC	Contains <i>Glycyrrhiza glabra</i> , <i>Bupleurum falcatum</i> , <i>Pinellia ternate</i> , <i>Scutellaria abaicalensis</i> , <i>Zizyphus vulgaris</i> , <i>Panax ginseng</i> , <i>Zingiber officinale</i>
Saiboku-to		Increased AUC	Same as above, with addition of <i>Poria cocos</i> , <i>Magnolia officinalis</i> , and <i>Perillae frutescens</i>
Betel nut (<i>Areca catechu</i>)	Prednisone, albuterol (salbutamol)	Inadequate control of asthma	Arecoline challenge caused dose-related bronchoconstriction
Cayenne (<i>Capsicum</i> spp.)	ACE inhibitors Theophylline	Cough Increased absorption and bioavailability	Capsaicin depletes substance P
Devil's claw (<i>Harpagophytum procumbens</i>)	Warfarin	Purpura	
Dan shen (<i>Salvia miltiorrhiza</i>)	Warfarin Aspirin Warfarin Paracetamol and ergotamine/caffeine Thiazide diuretic	Increased INR, prolonged PT/PTT Spontaneous hyphema Intracerebral hemorrhage Bilateral subdural hematoma Hypertension	Decreased elimination of warfarin in rats Inhibition of platelet adhesion factor May be due to ginkgo alone Ginkgo alone is not associated with hypertension.
GLA-rich herbs (evening primrose, black currant, borage)	Drugs that lower seizure threshold	Increased adverse effects	Decreased seizure threshold
Licorice (<i>Glycyrrhiza glabra</i>)	Prednisone	Glycyrrhizin decreases plasma clearance, increases AUC, increases plasma concentrations of prednisolone	Glycyrrhizin and its metabolite, glycyrrhetic acid, are inhibitors of 5 α ,5 β -reductase and 11 β -dehydrogenase (converts endogenous cortisol to cortisone)
	Hydrocortisone	Glycyrrhetic acid potentiates cutaneous vasoconstrictor response	
	MAOIs Oral contraceptives	Increased adverse effects Hypertension, edema, hypokalemia	Glycyrrhizin is an MAOI Oral contraceptives may increase sensitivity to glycyrrhizin
Nettles (<i>Urtica dioica</i>)	NSAIDs	Increased therapeutic effect	Potential of antiinflammatory activity
<i>Panax ginseng</i>	Warfarin Phenelzine Corticosteroids Estrogen replacement	Decreased INR Headache and tremor, mania Increased adverse effects Postmenopausal bleeding or mastalgia	Similar adverse effects
Papaya (<i>Carica papaya</i>)	Warfarin	Increased INR	
St. John's wort (<i>Hypericum perforatum</i>)	Paroxetine Trazodone Sertraline Nefazodone Theophylline Digoxin	Lethargy, incontinence Mild serotonin syndrome Mild serotonin syndrome Mild serotonin syndrome Decreased theophylline concentrations Decreased AUC, decreased peak and trough concentrations	Can occur with St. John's wort alone Most studies indicate that St. John's wort inhibits cytochrome P450 isoenzymes.
	Phenprocoumon Cyclosporin Oral contraceptives	Decreased AUC Decreased concentrations in serum Breakthrough bleeding	
Tamarind (<i>Tamarindus indica</i>)	Aspirin	Increased bioavailability of aspirin	
Yohimbe (<i>Pausinystalla yohimbe</i>)	Tricyclic antidepressants	Hypertension	Yohimbe alone is associated with hypertension; combination with tricyclics lowers active yohimbe dose

It is impossible to summarize all drug-herb interactions. Clinical data are sparse, uncontrolled, and often unreliable; most data are in the form of case reports, and information on dosage, temporal relations, contamination, and concomitant drug-herb use are often unreported. Moreover, the majority of the herb-drug interactions described in the literature are theoretical and have not been shown to occur in clinical practice; thus only clinically reported interactions are summarized here. In addition, the effects may depend on mode of ingestion; for example, effects may be stronger if an extract is used (e.g., standardized oil) than when herbs are incorporated into the diet (e.g., garlic cloves in food).

ACE, angiotensin-converting enzyme; AUC, area under the curve; INR, international normalized ratio; GLA, γ -linolenic acid; MAOI, monoamine oxidase inhibitor; NSAID, nonsteroidal antiinflammatory drug; PT, dilute prothrombin time; PTT, partial thromboplastin time.

Data from Fugh-Berman A. Herb-drug interactions. *Lancet* 2000;355:134-8; Deol CL, Schnitzer TJ, Lipstein E, et al. Treatment of arthritis with topical capsaicin: a double-blind trial. *Clin Ther* 1991;13:383-95; Hordy M. Herb-drug interactions: an evidence-based table. *Altern Med Alert* 2000;June:64-9.

nonsteroidal antiinflammatory drugs (NSAIDs), there exists the potential for interaction with anticoagulant medications, and patients taking these drugs should be monitored.

Ginger

The root of the ginger plant (*Zingiber officinale*) has been consumed and used medicinally in Asian cultures for thousands of years. Among its many

medicinal properties, ginger has demonstrated potent antiinflammatory effects, which are due in part to its high concentration of gingerols and salicylates. Studies show that ginger root targets inflammation through several different pathways (including prostaglandin activity and inhibition of 5-lipoxygenase enzyme,^{83,84} which may contribute to its ability to reduce pain. Four randomized controlled trials⁸⁵⁻⁸⁸ have found that ginger was superior to placebo in reducing pain scores, usage of analgesic medications,

and disability related to osteoarthritis. The dosage typically used in clinical practice is 1000 mg daily over a treatment period of at least 4 weeks. Although mild gastrointestinal distress may occur at higher doses, ginger is highly tolerable and adverse effects are rare. Ginger may interact with anti-coagulant medications, so caution should be taken in this regard.

Boswellia serrata

Boswellia serrata, also known as *Indian frankincense*, is a plant extract that has been featured as an important component of Ayurvedic medicine for thousands of years. As with many herbs used in the treatment of osteoarthritis, Western medicine has corroborated traditional usage because *Boswellia serrata* elicits potent antiinflammatory activity through its inhibition of the 5-lipoxygenase enzyme. Several forms of *Boswellia serrata* have been studied and used clinically, including traditional 60% to 70% extracts of *Boswellia serrata* gum resin and the commercial preparations 5-Loxin and Aflapin. Five randomized controlled trials have been conducted assessing the effects of *Boswellia serrata* extracts on osteoarthritis of the knee.⁸⁹⁻⁹³ All of these trials found statistically and clinically significant reductions in pain and improvements in physical function. Improvement in symptoms was noticed as early as 5 days after treatment commenced, and in one trial, these benefits persisted for 1 month following conclusion of treatment. Daily dosages used in these studies were 100 mg of Aflapin, 250 mg of 5-Loxin, and 333 mg of 65% standardized *Boswellia serrata* extract. *Boswellia serrata* was well tolerated in all trials, and aside from minor gastrointestinal distress in some participants, very few adverse effects were noted.

Herbal combination products

Practicing herbalists generally prescribe herbs in combination, and for this reason a variety of herbal combination products are available commercially. Of these products, the two for which the clinical evidence is most promising are SKI 306X (*Clematis mandshurica*, *Prunella vulgaris*, and *Trichosanthes kirilowii*),⁹⁴⁻⁹⁶ and Phytodolor (aspen [*Populus tremula*], common ash bark [*Fraxinus excelsior*], and goldenrod herb [*Solidago vigaurea*]).⁹⁷ Six randomized controlled trials of the herbal mixture Phytodolor showed significantly decreased pain,^{72,98,99} increased function,⁹⁸ and decreased need for rescue medication^{100,101} in patients with mixed rheumatic disorders, including osteoarthritis. A recent meta-analysis of 11 randomized controlled trials found that Phytodolor was superior to placebo in reducing pain associated with musculoskeletal disorders. The efficacy of Phytodolor in reducing pain did not differ statistically from that of NSAIDs, but it caused no major adverse events and far fewer minor adverse events than NSAID therapy.⁹⁷ Because of the paucity of high-quality trials, many herbs traditionally used by professional herbalists have not been investigated adequately (if at all). Further research is clearly needed.

Nutraceuticals and dietary supplements

The term *nutraceuticals* is a general classification that refers to the wide array of biologically based products available to health practitioners and consumers; they include vitamins, minerals, neurotransmitters, hormones, animal products such as shark cartilage and glandular preparations, and other naturally occurring substances such as glucosamine and S-adenosylmethionine (SAM-e). The sheer number of these products can be overwhelming to practitioners and consumers alike; to date, the efficacy and safety of most of these therapies have not been thoroughly investigated. However, there are several nutraceuticals for which a substantial evidence base is beginning to emerge in the treatment of rheumatic and musculoskeletal diseases, most notably glucosamine and chondroitin, SAM-e, and essential fatty acids.

Glucosamine and chondroitin

Current research suggests that glucosamine and chondroitin may be chondroprotective agents.¹⁰² Both are constituents of connective tissue and are capable of increasing proteoglycan synthesis in articular cartilage.¹⁰³ In addition, glucosamine and chondroitin appear to regulate gene expression of nitric oxide and prostaglandins involved in osteoarthritis.¹⁰⁴ Moreover, despite controversy in this area, both substances appear to be absorbed intact in the digestive tract and have a minimal adverse effect profile.^{102,105,106} Numerous narrative and meta-analytic reviews indicate that glucosamine, either combined with chondroitin or alone, is an effective treatment for osteoarthritis.¹⁰⁷⁻¹⁰⁹ Towheed and colleagues¹⁰⁹ reviewed 16 randomized double-blind studies and found glucosamine to be significantly more effective than placebo and more effective than or equal to NSAIDs with minimal adverse effects. McAlindon and associates¹⁰⁸ reviewed randomized trials of both glucosamine and chondroitin and found moderate to large effect sizes; modest yet positive effective sizes were found when methodologically weak studies were excluded and results were recalculated for outcomes at

4 weeks. A randomized controlled trial (n = 212) published since the aforementioned reviews¹¹⁰ has shown that patients taking 1500 mg of oral glucosamine sulfate daily over 3 years experienced no significant joint space loss and minimum joint space narrowing compared with patients receiving placebo.

The large Glucosamine/Chondroitin Arthritis Intervention Trial (GAIT)¹¹¹ funded by the National Institutes of Health compared glucosamine alone, chondroitin sulfate alone, glucosamine/chondroitin sulfate, and celecoxib with placebo. Participants in the glucosamine/chondroitin group did not demonstrate a statistically significant improvement compared with the placebo group in primary outcome (20% improvement in WOMAC pain score) in the overall study sample of patients with osteoarthritis of the knee. Some 66.6% of the overall study sample in the glucosamine/chondroitin group experienced at least a 20% improvement in pain, and the lack of statistical significance was thought by the authors to be due to the surprisingly high improvement in the placebo group (60.1%).¹¹²

Although the findings of the more than 50 randomized controlled trials of the use of glucosamine/chondroitin in osteoarthritis have not been universally positive, consideration of the totality of the evidence suggests that glucosamine/chondroitin is a safe and at least moderately effective treatment for osteoarthritis. A daily dose of 1500 mg glucosamine and 1200 mg chondroitin has been studied most often and is the typical recommended dosage.

S-adenosylmethionine

SAM-e originally was used to treat depression,^{113,114} and the effects of SAM-e on joint pain were discovered serendipitously when they were observed as side effects in clinical trials. Produced from L-methionine and adenosine triphosphate, SAM-e is a methyl donor involved in a wide variety of metabolic processes throughout the body.¹¹⁵ Although the mechanism of action is not completely understood, SAM-e has been shown to have antiinflammatory and analgesic effects without gastrointestinal damage in animal models¹¹⁶; *in vitro*, SAM-e has exhibited chondroprotective effects via the stimulation of chondrocytes and the subsequent increase in new cartilage production.¹¹⁷

A meta-analysis of 13 trials investigating SAM-e in the treatment of osteoarthritis¹¹⁸ indicated that SAM-e is comparable to ibuprofen and superior to placebo. A large randomized controlled trial published after this review compared the efficacy of SAM-e with that of celecoxib in patients with osteoarthritis.¹⁰⁴ The study found that despite a slower onset of action, SAM-e was as effective as celecoxib in relieving pain and improving physical function after 16 weeks of treatment. SAM-e has no known adverse effects,¹¹⁴ but the long-term effects are unknown. Most clinical studies to date have used a daily dosage of between 400 and 1600 mg.

Essential fatty acids

Essential fatty acids, including ω -6 fatty acids—linolenic acid (LA) and γ -linolenic acid (GLA)—and ω -3 fatty acids— α -linolenic acid (ALA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA)—are the first components of a physiologic cascade that results in prostaglandin, leukotriene, and thromboxane production.¹¹⁹ Specifically, the presence of ω -3 fatty acids can antagonize the cellular biosynthesis of prostaglandins E₂, interleukin-1 β , leukotriene B₄, and tumor necrosis factor^{120,121}; these compounds play an important role in the pathophysiology of rheumatoid arthritis.¹²² Moreover, ω -3 fatty acids may inhibit the platelet-activating factor synthesis pathway, the cyclooxygenase pathway, and the 5-lipoxygenase pathway.¹²³

The ω -3 fatty acids have been shown in numerous reviews to improve rheumatoid arthritis symptoms.^{121,124-126} In addition, multiple studies indicate that ω -3 supplementation can reduce dependence on NSAIDs and antirheumatic drugs¹²⁷⁻¹³⁰; however, additional studies are needed before definitive conclusions can be made.¹²¹ No significant toxicities have been associated with their use.¹³¹

The ω -3 fatty acids are found in fish oils (EPA, DHA), leafy green vegetables (ALA), and plant oils such as flaxseed, rapeseed, and walnut oils (ALA); although all forms are important, EPA and DHA are more easily utilized by the body,¹³² because conversion from ALA to EPA and DHA is poor. For this reason, the optimal forms of ω -3 fatty acids taken for therapeutic purposes in rheumatic conditions are EPA and DHA. To date, most studies have investigated the effects of fish oils; these studies show that a minimum daily dosage of 3 g of EPA and DHA is required for clinical efficacy, and benefits become apparent after a minimum of 12 weeks.¹²¹

In addition, there is evidence for the efficacy of certain ω -6 fatty acids¹¹⁹; these, however, are generally administered in the form of herbal extracts of evening primrose, borage, or black currant.^{78,133,134} In a systematic review Little and colleagues¹³⁵ examined herbal interventions using herbs rich in GLA to treat rheumatoid arthritis. Compared with placebo oils (olive oil,

sunflower oil, cottonseed oil, liquid paraffin, and soybean oil), the oils containing GLA significantly improved joint tenderness, swelling, stiffness, and functionality.

Avocado/soybean unsaponifiables

Avocado/soybean unsaponifiables (ASU) is a compound consisting of the unsaponifiable oils (remnants after hydrolysis that do not form soap) of avocado and soybean. ASU is composed of one third avocado and two thirds soybean unsaponifiable oils. An extensive body of literature supports ASU's antiinflammatory properties, including blocking the activation of cyclooxygenase-2 transcripts and the secretion of prostaglandin E₂ as well as inhibiting the inflammatory cytokines tumor necrosis factor- α and interleukin-1 β .¹³⁶ ASU has also demonstrated the ability to stimulate the synthesis of collagen in human joint chondrocyte cultures.¹³⁷ The efficacy of ASU in improving osteoarthritis of the knee and hip has been evaluated in four randomized controlled trials that were the subject of a meta-analysis.¹³⁸ Three of these trials found that ASU was significantly more effective than placebo in improving osteoarthritis symptoms, whereas the fourth found no significant improvement compared with placebo. Meta-analysis of data from these studies (n = 664) found that twice as many participants in the ASU groups as in the placebo groups reported improvement in symptoms (reduced pain and increased ability to perform activities of daily living). ASU was associated with very few adverse effects in these studies. The typical dosage was 300 mg/day.

Homeopathy

Homeopathy is probably one of the most widespread, and certainly one of the most controversial, whole-system approaches within CAM. It involves a long and involved consultation and a prescription of often very dilute, indeed in some cases ultramolecular, "medication." The first principle of homeopathy is the idea of similars: this principle states that patients who have particular signs and symptoms can be cured if they are given a homeopathic medication that produces the same signs and symptoms in a healthy individual. Homeopathy is designed around the concept of picture-matching the patient's symptoms with a drug picture produced by a homeopathic remedy, and the idea of "like cures like" is derived from this concept. The second principle, and probably the most confusing to orthodox physicians, is the serial dilutions and shaking of a medication, often until the medication contains no molecules of the original product. Homeopaths suggest

that the medication still retains its effects even though it is ultramolecular (diluted beyond the Avogadro number). Homeopathy therefore confronts conventional science at its core, and many believe that homeopathic medicines can have no more than a placebo effect. The reason for including homeopathy in this chapter is not to provide conclusive evidence that it "works" in arthritic conditions but to illustrate some of the problems and debates that are confronted within CAM research.¹³⁹

Evidence

Jonas and colleagues' systematic review¹⁴⁰ of the quality of homeopathic clinical trials encompassed 59 studies of various homeopathic treatments for conditions ranging from stroke, postoperative complications, arthritis, and fibromyalgia to influenza. The studies in rheumatology indicate an odds ratio that, overall, significantly favors homeopathy but clearly suggests that there is currently inadequate evidence to make specific claims about the use of homeopathy to treat any particular condition. The debate about the evidence for clinical effects of homeopathic medicines is amply illustrated by two other systematic reviews that analyzed much the same clinical trial data and came to entirely opposing conclusions.^{141,142} When this occurs, and minor changes in the methodology of a systematic review can have such a profound impact on its conclusions, we must step back and realize that we have too little data on the specific effects of the remedy to be definitive.

REFERRAL AND PROFESSIONAL PRACTICE

Above all, physicians need to initiate an open dialogue with their patients about CAM therapies; more than 70% of patients who use CAM do not inform their physician that they are doing so.¹⁴³ Many patients use both conventional and CAM modalities simultaneously to manage their chronic problems.¹⁴³ When discussing CAM use with patients, it is important to remain neutral, because negative attitudes or application of labels such as "unorthodox" may discourage patients from discussing CAM use¹⁴⁴ or even create polarization that causes them to abandon good-quality conventional care.¹⁴⁵ Moreover, issues of safety and efficacy (of both conventional and CAM options) should always be reviewed, and patient preferences and expectations should be discussed and documented. This will allow patients and physicians to make responsible decisions *together* about treatment options and jointly monitor progress with the CAM provider.

Placebos, caring, and healing in rheumatology

■ PAUL DIEPPE ■ DEBBIE MARSDEN ■ SARAH GOLDINGAY

- Chronic rheumatic diseases are complex and occur in different, and changing, social and cultural contexts. Linear cause-and-effect models may not be appropriate for their explanation or management.
- The placebo response has a powerful influence on symptoms such as pain and is responsible for the majority of the beneficial effects seen from symptomatic therapy.
- Nocebos have very powerful negative effects on symptoms. Health anxiety is a key mediator of the nocebo response.
- Prior expectations and conditioning are important mediators of both placebo and nocebo responses.
- Placebo and nocebo administration can cause release of neurotransmitters and other changes in brain function (detected by functional magnetic resonance imaging) that may explain their actions.
- Caring, compassion, empathy, and validation improve symptoms and can relieve pain.
- The polyvagal, nurturing (safety) response provides a neuroregulatory theory to help explain the value of caring and relationships in health care.
- Humans live in stories (narratives) and have to find ways of including illness within those narratives. Helping them achieve this can reduce distress.
- Some medical narratives (e.g., "You have medically unexplained symptoms") are incompatible with patients' need to reduce health anxiety and make meaning of their problems.
- Beneficial, profound transformational changes are sometimes observed in patients. This is called the *healing response*. Positive human interactions appear to be a critical way of facilitating a healing response.

INTRODUCTION

Whether medicine should be regarded as an art, a science, or both has been debated for centuries¹; perhaps it is an art nested within science. Current mainstream Western medicine is certainly dominated by the sciences, particularly biomedical science, as this and most other textbooks testify. This chapter is more about the art of being a rheumatologist than the science of rheumatology. But it also discusses some of the science that is helping us understand the central importance of context, caring, relationships, stories, and healing in medicine.

CONTEXT AND COMPLEXITY

Medicine, like everything else, takes place within a cultural context that shapes the beliefs and behaviors of its practitioners and patients. Over time, a plethora of different approaches and systems for health care have been developed. Currently, in the developed world, we have largely excluded all but one of these (biomedicine), and indoctrinated ourselves and the public into thinking that it is the only "reasonable" approach to health and illness.^{2,3}

Our biomedical view of the world is based in positivist, reductionist philosophy.⁴ It is generally thought that if we can break the body down into its constituent parts and understand how each bit works at a molecular level, we will then be able to find answers to problems that arise with our bodies.

We believe that this approach can "fix" things. We take a linear view of causality, believing that one thing will predictably cause another.

This reductionist biomedical approach has served us well in dealing with infectious disease and many of the acute medical problems that affect our species. But it does not work well for chronic disease. Complexity science teaches us that linear cause-and-effect models are not good at predicting outcomes in complex systems and that any attempt to induce change in such systems is likely to have unpredictable outcomes and result in strange "emergent properties."⁵ Chronic diseases are certainly complex. Chronic ill health is generally related to a multifactorial mix of cultural influences, social problems, and psychological issues affecting an individual trying to function within a complex social system, sometimes complicated by the presence of an organic disease; and yet we continue to use single interventions to affect the disease element alone, in the hope that this will result in predictable improvements in health status. Quantum theory has made many theoretical physicists move away from the reductionist model, and it may be time that medical science do the same thing and consider alternative paradigms such as realism.⁶

CLINICAL TRIALS AND THE PLACEBO AND NOCEBO RESPONSES

One of the main methods used in our reductionist biomedical approach to health care, and in evidence-based medicine, is the randomized controlled trial (RCT).⁷ Since the 1950s RCTs have been seen as the best way of testing whether a drug is effective and, importantly, more effective than dummy pills (placebos), which might make people imagine that they were getting better in the absence of an active ingredient.⁸ However, trialists soon found that people given dummy pills often got better and that this "placebo response" was not confined to unintelligent, gullible people, as had previously been assumed.⁹ Such a finding was not helpful to investigators looking at the effect of a specific intervention, and the placebo response became something to adjust for in the analysis of trial outcomes.⁸ As drugs and science have improved, it has been considered unethical to include no-treatment groups in trials. Consequently, there often is no true comparator for the effects that result when people are given a placebo treatment. This has allowed some to deny the very existence of the placebo response.¹⁰ However, many recent studies have confirmed the symptomatic value of placebos in different contexts.^{11,12}

A systematic review of trials of interventions for pain in osteoarthritis in which a no-treatment control group was included was published in 2008.¹³ This review illustrated the power of placebo, because the effect size on pain in such three-arm trials (active drug, placebo, and no treatment) was between 0.5 and 0.7, considerably larger than the effect sizes of around 0.2 to 0.3 that is achieved with most active treatments. Others have obtained similar results from the analysis of trials of antidepressant drugs.¹⁴ So, the placebo response accounts for the majority of the benefit that patients gain from analgesic or antidepressant therapies.

A placebo, by definition, has no active ingredient that can have any specific effect on the target problem—it cannot *do* anything.¹⁵ It is the context in which treatments are given that is responsible for placebo effects. It is a response dictated by the expectations and beliefs that the patient brings, the environment in which the treatment is administered, and the behaviors and rituals of the health professionals who administer it.¹⁶ An RCT is a highly artificial experiment in which investigators try to "control" for many of these factors, so it may underestimate the power of context. Paterson and Dieppe¹⁷ hypothesize that this is particularly likely for interventions in which there is an interaction between the behaviors of the health professional and the intervention itself, such as physiotherapy and most

Fig. 48B.1 Treatment effects can be divided into characteristic effects (the specific effect of the intervention on the target disorder) and incidental effects (also called *placebo effects*, *context effects*, or *meaning effects*). The incidental effects are a complex combination of all factors that affect the outcome other than the characteristic effects of the intervention and include interactions between therapist and patient and a wide variety of other contextual and environmental factors. For symptoms such as pain and depression the size of the incidental effect is often larger than that of the characteristic effect. In many complex interventions, such as physiotherapy, there is an interaction between the characteristic element (e.g., muscle strengthening) and incidental elements (e.g., the ability of the physiotherapist to motivate the patient to do the exercises). This can lead to underestimation of the effect of an intervention if a classical randomized controlled trial design is used, because such trials measure only the difference between the effects of characteristic and incidental elements. (Adapted from Doherty M, Dieppe P. The “placebo” response in osteoarthritis and its implications for clinical practice. *Osteoarthritis Cartilage* 2009;17:1255-62; and Paterson C, Dieppe P. Characteristic and incidental (placebo) effects in complex interventions such as acupuncture. *BMJ* 2005; 330:1202-5.)

complementary and alternative (CAM) therapies (Fig. 48B.1). If Paterson and Dieppe are right, it suggests that we should not be using the simple RCT model to investigate such interventions because it will systematically underestimate their effects (and facilitate the sceptics’ dismissal of all CAM as useless nonsense).

Nocebo effects and the importance of anxiety

The *nocebo* response has been described as the “evil twin” of the placebo response¹⁸ and can be very powerful, as voodoo deaths indicate.¹⁹ Nocebo has been the subject of much less research than placebo, but it is clear that just as positive expectations and suggestions can help induce beneficial responses to an intervention in the absence of any active ingredient, so negative expectations and suggestions can make things worse.¹⁸ As with placebos, the whole context matters, including the environment—but especially what is said.²⁰ Anxiety appears to be one of the key mediators of a powerful *nocebo* effect.²¹ Negative emotions, particularly health anxieties, induced by a health care encounter can exacerbate symptoms and block the effects of drugs such as analgesics.²²

The science of the placebo and *nocebo* responses

There are two main psychological theories about placebo: conditioning and expectations.²³ A *conditioned response* occurs when the brain gets used to the pairing of stimuli; in the classical pavlovian conditioning experiments, dogs came to associate the ringing of a bell with the provision of food and would then salivate immediately when the bell was rung. In more recent experiments it has been shown that volunteers can be conditioned to induce immunosuppression in response to a novel green drink if it has previously been paired with the administration of cyclosporine A.²⁴ Such work raises the exciting possibility of achieving immunosuppression without high doses of drugs.^{25,26} Conditioning may also explain phenomena seen in rheumatology, such as a patient’s experiencing the same adverse effects to every drug that the patient tries: the patient has been conditioned to have that adverse effect to tablets.

Cognitive expectations have been researched extensively. For example, people will respond to coffee with a psychological and physiologic response characteristic of a caffeine shot if they think the coffee is caffeinated, even if it is not.²⁷ Similarly, one can observe a graded response to a placebo

analgesic cream applied to the skin with a progressively stronger assurance that the cream will block the pain induced by an algometer.²⁸

There is also compelling *biochemical evidence* that placebo administration (and the rituals surrounding it) can lead to the release of neurochemicals such as dopamine and endogenous opioids that have a direct effect on the brain resulting in suppression of disease-related symptoms.^{18,23} Functional magnetic resonance imaging studies are also helping to describe neurologic mechanisms that underlie this intriguing phenomenon.²⁹ Finally, as outlined later, the social sciences are contributing to our understanding of the placebo response.

CARING AND RELATIONSHIPS

In 1927 Francis Peabody’s landmark article “The Care of the Patient” was published.³⁰ Peabody expressed concern that science within medicine might be marginalizing the central importance of caring; he famously concluded that “the secret of the care of the patient is in caring for the patient.”

Peabody was writing well before the scientific revolution in medicine, and more recently many other authors have expressed concern that science is marginalizing caring, that physicians have turned into body “mechanics” rather than carers, and that physicians have forgotten their core values.^{31,32} However, core values and caring have continued to be major concerns in nursing literature, where many theories of caring, such as Watson’s “*carative*” factors,³³ have been developed.

In medicine more emphasis has been given to concepts such as relationship-centered care,³⁴ caring in the community, and the role of carers.³⁵ Although caring may not have been at the forefront of biomedical thinking in recent years, no one would deny its central importance to health care. Each of us has experienced the value of being cared for by another during times of distress.

The science of caring

Compassion, empathy, and validation

There has been a lot of research on the importance of compassion and empathy in health care encounters.^{36,37} *Physician empathy* has been defined as the understanding of the patient as well as verbal and nonverbal communications that result in changes in patient behavior³⁷; this definition

views it as the creation of a relationship that facilitates appropriate use of treatments. However, the creation of a good relationship can go further than that. It can facilitate healing, as discussed later in this chapter. The neurobiology of empathy has also been the subject of a good deal of research, much of it concerned with mirror neurons (the system that facilitates imitation of the gestures of others).³⁸ It appears that not only are embodied actions created by the mirroring representation systems in the brain, but we work cognitively to achieve empathy; we take the perspective of others and imagine their problems and feelings.

Validation (and its opposite—invalidation) goes further than empathy. Validation of another is more about communicating your understanding to the other, rather than just being compassionate or empathetic. It emphasizes the position of the recipient—his or her interpretation of and feelings about the interaction that has taken place.³⁹ The sense of being validated or understood has been shown to affect symptoms such as pain. For example, one study found that participants experiencing chronic back pain who received invalidating feedback during a semistructured interview reported higher levels of negative affect, higher pain intensity, more frustration, and lower levels of patient satisfaction than participants in the group receiving validating feedback.⁴⁰

The nurturing response

The fight-or-flight response is a reaction to perceived threats; it activates the sympathetic part of the autonomic nervous system, the release of adrenaline, and profound physiologic and emotional changes. Porges⁴¹ has described the neurophysiology of its opposite, the “nurturing response.” This response is activated by perceived safety and results in parasympathetic activation, calmed emotions, and relaxation. It is this nurturing response that helps people to care for their young (witness the response of anyone seeing a young baby smile) and work together in effective groups in a collaborative way.⁴² The muscles of facial expression and voice production are linked into this polyvagal system: when the threat response is activated people’s faces become less expressive and their voices flat, whereas when the nurturing (safe) response is active they express their emotions through their faces, have more expressive voices, and are better able to interpret the emotional state of someone they are interacting with.^{41,42} Therefore whether the individual is feeling safe or threatened during a health care consultation has a huge effect on the interactions and outcome. It is sobering to consider how often our patients are likely to be in the threat mode while in our consulting rooms, and how often the doctors and nurses themselves feel threatened. No wonder communications often fail and caring for and nurturing another person can be absent from a clinical encounter.

Clearly, we need to be able to make sure that we as clinicians, as well as our patients, are in a safe place during a consultation (Fig. 48B.2).

HEALTH, SUFFERING, HEALTH BELIEF, STORIES, AND MEANING

The World Health Organization defines health as “a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity.” But, as Petr Skrabenek pointed out, such a state is rarely achievable—it is “the sort of feeling ordinary people may achieve fleetingly during orgasm, or when high on drugs.”³¹ Life is a process with its ups and downs, and symptoms such as aches and pains are a part of it. Distress, grief, and suffering are also things that we all experience from time to time. The idea of health as “complete” and static is untenable.

How much we worry about our everyday symptoms, such as aches and pains, and whether we take them to a doctor or not, is dictated by a mixture of social, cultural, and psychological factors. Our health beliefs and the stories we live in affect the response we have to arthritis and the drugs prescribed for it.⁴³ For example, a study of people who reported symptoms of severe lower limb arthritis but had not sought medical help found that many regarded their arthritis as part of their identity or as an inevitable result of the ways in which they had led their lives.⁴⁴ Emerging methods such as narrative-based medicine take a particular approach to eliciting and understanding the stories patients live in and the way in which those stories shape their response to disease.⁴⁵

Moerman has coined the phrase *meaning response* to extend this idea of stories, combining the placebo response with narrative-based medicine and the human need for meaning in life.^{46,47} He cites a number of examples to illustrate the ways in which the meaning that a certain intervention has to an individual shapes the individual’s response to it. One striking example is the response to dummy (placebo) pills that are either red or blue. If told that one color is a sedative and the other excitatory, most people will get sleepy when given the blue one and excited when given the red one. In Italy,

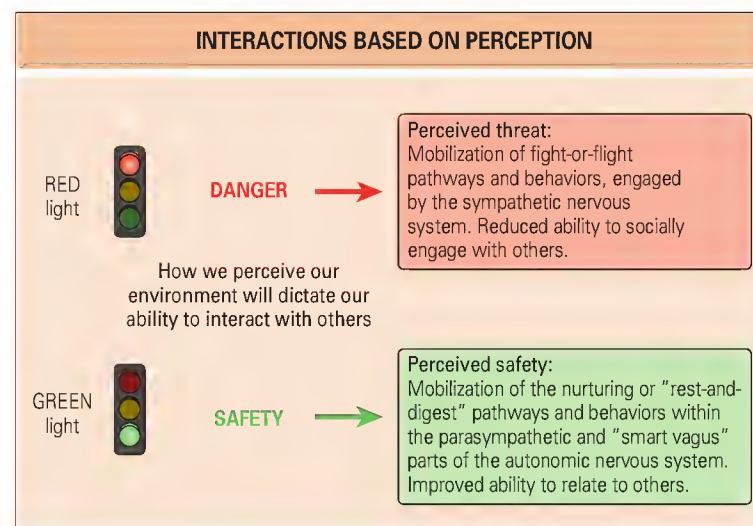

Fig. 48B.2 We are constantly monitoring our environment to see if any threats are present. If we feel threatened, then the fight-or-flight response is activated, which results not only in physiologic changes to the cardiovascular system, but also to changes in the ability to communicate effectively with others. In contrast, if we feel safe, the nurturing response is activated. We then feel calmer and more relaxed, we are more receptive to information and advice from another, and our feelings are expressed more fully through facial expression and tone of voice. Good clinical interactions, therefore, are facilitated when both the clinician and the patient feel safe. Unfortunately, hospitals and physicians are often threatening. (Adapted from Porges SW. *Social engagement and attachment: a phylogenetic perspective*. *Ann N Y Acad Sci* 2003;1008:31-47; and Porges SW. *The polyvagal theory: neurophysiological foundations of emotions, attachment, communication and self-regulation*. New York: WW Norton; 2011.)

however, it is the other way around, and Moerman speculates that this may be because the national football team plays in blue uniforms.⁴⁷

We have to find meaning to our existence; it is not surprising, then, that we fit abnormal symptoms or changes in our bodies into our stories.^{45,48} Physicians take a different approach—they try to fit the experiences described into a diagnostic category so that they can label the patient as having a disease.⁴⁹ If the physician cannot make biomedical sense of the patient’s dilemma and “box” it into a diagnosis, she or he is likely to label it “medically unexplained physical symptoms,” a negative term implying that biomedicine does not yet understand the patient’s problem but that some further tests or a different physician might be able to find the cause. This approach seems designed to engender anxiety and “doctor shopping.” It leaves the patient in a difficult place—and, of course, all symptoms in all conditions are medically unexplained from the patient’s perspective.

The designation of conditions such as fibromyalgia as “medically unexplained” illustrates another issue for modern biomedicine: its difficulty with the cartesian split between mind and body. Patients have the same difficulty. If a patient with chronic widespread pain is encouraged to see a psychiatrist, the patient may respond angrily, “So you think it’s all in the mind, then, do you?” which indicates that the patient views mental and physical problems as different things. Physicians often fall into the same philosophical trap.

Recent research comparing conditions for which medicine can find an organic explanation with those for which it cannot has shown that there is very little difference in their effect on quality of life or utilization of services, but that it is the number of symptoms experienced by the patient and the patient’s levels of anxiety that predict health status.⁵⁰ The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* reclassifies medically unexplained physical symptoms as somatic symptom disorders,⁵¹ which may help both physicians and patients deal with the stigmatization that can result from the label “medically unexplained symptoms.”

TRANSFORMATIONAL CHANGE AND THE HEALING RESPONSE

Physicians often witness extraordinary, unexpected, transformational changes in a patient. Someone who seems to have an incurable or untreatable disease problem changes for the better for no apparent reason, a change that can occur relatively quickly or over a period of weeks, months, or years. We call this the *healing response*, the activation of the natural ability of the

body, mind, and soul of a person to regain balance and congruence after a period of disturbance or disruption. Just as we are all hard-wired for nurturing and caring for others, we all have the intrinsic ability to self-heal from many conditions, to regain the homeostasis that all living organisms seek.⁵²

Healing has been defined in many different ways. In the medical literature it is used largely to describe bodily healing alone (the healing of wounds or the repair of a fracture), but in the CAM, lay, and healing literature it has a much wider meaning and is used to describe wholeness and the integration of body, mind, and spirit (Box 48B.1).⁵³⁻⁵⁷

The science of healing

The preceding sections have emphasized that there is plenty of hard science to support the notions of placebo and nocebo responses, and the value of caring. Is there any science to support the concept of healing?

There are systematic reviews which report a beneficial effect in trials.⁵⁸ Furthermore, much of what is considered healing might be a part of the placebo response, related to rituals and embodied experiences, facilitated by validation, or enhanced by induction of the polyvagal safety response, described earlier. But perhaps there is more to it than that. All societies and cultures have had their healers and healing rituals,⁵⁷ and most emphasize something more than just bodily healing, something more spiritual or metaphysical. The healing community emphasizes the concept of energy flow,⁵⁹ a concept that also has some scientific evidence behind it,⁶⁰ and one that is important to other medical systems such as Chinese traditional medicine or Indian ayurveda.⁵⁷ In their scientific examination of what might be termed *anomalous healing experiences* Krippner and Achterberg cite a 1958 joint British Medical Association and Anglican archbishop's commission looking into unusual healing which concluded that "we cannot afford ... to disregard any means at our disposal which may lead to the restoration of ... health."⁶¹ Perhaps, as Hamlet said to Horatio, "there are more things in heaven and earth than are dreamt of in [our biomedical] philosophy."

CONCLUSION

Symptoms and their meaning are what matter to patients, and the more symptoms they have and the more anxious they are about them, the more likely it is that their health will be compromised. Rheumatologists need to listen to symptoms, ask about symptoms that have nothing to do with the musculoskeletal system, ask patients what they think are the causes of these symptoms, and ask how serious patients believe them to be and how much they worry about them. We need to listen to the answers, so that patients feel heard and validated, and help patients to make sense and meaning of what is going on. And above all else, we must try to make patients feel safe; reduce health-related anxieties rather than increasing them with investigations and treatments of borderline value; and thus avoid the nocebo effect and make way for the beneficial placebo and healing responses.⁶²

BOX 48B.1 THE HEALING RESPONSE

Healing is a slippery concept that is difficult to define or recognize because it is an intensely personal experience that gets to the core of one's identity and spirit. It is a process that comes from within a person rather than being dependent on a specific intervention. This box notes what some of the different descriptors are in the literature and what some authors who have studied healing consider to be the keys to facilitating healing in the context of a modern health care encounter.

Some descriptions of healing

Various authors

- A process of restoration of the whole person
- Reachieving balance and homeostasis
- Bringing together of body, mind, and spirit

Egnew (2005)⁵³

- A reconciliation of the meaning an individual ascribes to distressing events with his or her perception of wholeness as a person
- The personal experience of the transcending of suffering

Csardas (2002)⁶³

- The transformation of a person, a self that is a bodily being

Kirmayer (2004)⁵⁶

- From feeling ill to wellness, from afflicted to healed

Some facilitators of healing

Various authors

- Total attention with good intention—or the intentional beneficial influence of one person upon another without the use of a specific intervention

Scott et al (2008)⁵⁵

- Creating a nonjudgmental emotional bond
- Consciously managing clinician power to the benefit of the patient
- Displaying a commitment to caring over time

Churchill and Schenck (2008)⁵⁴

- Doing the little things
- Taking time
- Being open and listening
- Finding something to like, to love
- Removing barriers
- Letting the patient explain
- Sharing authority
- Being committed

Drug development

■ LACHY McLEAN

- Drug development is the process of bringing a new therapeutic molecule from preclinical studies through to regulatory approval and availability to the patient and prescriber.
- Before human clinical studies are begun, extensive preclinical research is performed on new drug candidates to validate the target, optimize the molecule, understand potential toxicities, predict key properties in humans, and devise translational biomarkers.
- Clinical development is divided into phase 1 (single and multiple rising dose studies, drug interaction studies), phase 2 (proof of concept, dose-ranging studies), and phase 3 (confirmation of efficacy and safety). Clinical trial duration, size, and cost increase progressively.
- Phase 1 studies typically are done in healthy volunteers for small molecules and in patients for biologics.
- Drug development is lengthy and expensive, and the risk of failure is high.

INTRODUCTION

Drug development is the process of bringing a new drug molecule into clinical practice. In its broadest definition this encompasses all steps from the basic research process of finding a suitable molecular target to supporting the commercial launch of the drug. In a narrower sense, *development* refers only to the clinical parts of this process, with *discovery* used to describe the nonclinical research components; this topic is rich in jargon that is used in different ways by different companies and individuals.

This chapter focuses on key aspects that rheumatologists are likely to encounter as investigators in clinical research trials and as expert advisors to industry. More details of the pharmaceutical research and development process can be found in standard texts and in the many guidance documents produced by regulatory authorities and other professional bodies.¹

PRECLINICAL RESEARCH

Target validation

The discovery and clinical development of a new drug may be broken down into several parts (Fig. 49.1). Preclinical research generally begins with the identification of a drug *target*, a molecule thought to play a crucial part in the pathogenesis of a disease of interest. The target may be truly novel (the product of the company's own basic research) or may have entered the public domain through scientific publications or a patent. Many factors must be considered in the choice of a "good" target (Box 49.1).

The early steps in preclinical research focus on *target validation*: characterizing the target and its putative role in disease and in normal physiology. Key components of validation for a new rheumatology target may include analysis of its place in molecular pathways known to be involved in inflammation or immune cell signaling; an exhaustive review of published scientific and patent literature; demonstration of the target in relevant tissues (e.g., increased expression in rheumatoid synovial tissue); study of the effects of an inhibitor on patients' peripheral blood or synovial cells *in vitro*; and use of animal models of arthritis. A targeted genetic deletion (knockout) of the prospective drug target or a knockdown using RNA interference may

help establish the role of the target both in normal physiology and in disease models.

Clinical precedents

A further element of validation may come from prior clinical experience with earlier drugs affecting the target itself or other parts of the molecular pathway. For example, the efficacy of anti-interleukin-17 in managing inflammatory disorders supports exploration of small-molecule drug approaches against retinoic acid receptor-related orphan nuclear receptor (ROR γ t), a transcription factor crucial for type 17 helper T lymphocytes.

Early knowledge of potential toxicities can permit early termination of research efforts on a target. Many companies shy away from targets that may affect prostanoid pathways or peroxisome proliferator-activated receptor- γ because of prior associations with major adverse cardiovascular events.

Drug discovery

The starting point for creating a small-molecule drug for a new target may be a high-throughput screen. Robotic samplers and microwell plates are used to test a large library of *drug-like small molecules* (approximately 500 Da) for binding to a known target or for activity in a biologic system. Medicinal chemists then use the most promising molecules identified in this way ("hits") as the starting point for designing a drug molecule suitable for further *in vitro* and animal testing. The resulting drug-like candidates are sometimes referred to as *leads*, and the next layer of improvements as *lead optimization*. Advances in x-ray crystallographic techniques have led to *structure-based* and *fragment-based drug design*, in which assembly of the new molecule is steered by the three-dimensional structure of the target.

A drug that binds its target with a tighter fit and higher affinity will require lower concentrations to inhibit the target and is less likely have undesirable activity against related targets. Desired affinities for new small-molecule drugs are usually in the low nanomolar range. Drug molecules are also tested for the ability to impair the function of the target (e.g., the enzymatic activity of a kinase) using *in vitro* cell-based systems.

Druggable targets

Small-molecule drugs can affect a target only if they get access to a specific part of the molecule—ideally a small cleft or pocket at a site critical to the molecule's function—and bind strongly enough to affect its behavior. Around 10% of the human genome represents such "druggable" targets, but only 5% of these targets are both druggable and relevant to human disease.² Past success with related targets, for example *protein kinases* (see Chapter 64) and *G protein-coupled receptors*, goes some way toward predicting future success. Certain structural features may also help predict the ability to optimize the fit of a small-molecule drug to a new target.³ These concepts are likely to change as new techniques are developed.

Drug optimization

A good small-molecule drug must also be absorbed well from the gastrointestinal tract, distributed to parts of the body where it is needed, and remain at the site of action long enough.⁴ Common issues are poor oral absorption, rapid elimination by hepatic metabolism, and failure of the drug to penetrate cells or its quick removal by efflux pumps. The key pharmacokinetic (PK) properties of *absorption*, *distribution*, *metabolism*, and *excretion* are assessed in preclinical species, and the equivalent parameters in human are estimated by *allometric scaling*.

Fig. 49.1 Progression of a new drug through clinical development is divided into three main phases. Phase 0 work (e.g., biomarker development) may be done in parallel with preclinical testing. Phase 1 studies other than single rising dose (SRD) and multiple rising dose (MRD) studies are usually done in parallel with phase 2 or 3. Clinical trial duration and the number of subjects in each phase (N) varies according to the indication and any specific issues with the drug. Red stars indicate key regulatory steps. *Or equivalent outside the United States. BLA, biologic license application; DDI, drug-drug interactions; EOP2, end of phase 2 (agency meeting); IND, investigational new drug; NDA, new drug application; OLE, open-label extension; PoC, proof of concept; QoL, quality of life.

BOX 49.1 FACTORS CONSIDERED IN CHOOSING A DRUG TARGET AND INDICATION

Target characteristics

Target validation/role in disease
Role in physiology
Phenotype of knockout/knockdown
Preclinical disease model
Structurally enabled (crystallography)
Precedent for inhibiting pathway
Novelty of mechanism
Target polymorphisms
Pharmacodynamic biomarker

Availability of good study sites

Companion diagnostic
Validated endpoints

Regulatory pathway

Perceptions of disease severity and impact
Approval precedents
Guidance document(s)

Commercial attractiveness

Number of eligible patients
Unmet medical need
Competitive landscape (existing and pipeline)
Patent loss-of-exclusivity timeline
Pricing potential

Clinical development pathway

Patient definition (accepted criteria)
Disease heterogeneity
Standard-of-care therapy
Disease-proximal biomarkers
Availability of clinical trial patients

Biologics

The protein therapeutic agents used in rheumatology are generally either monoclonal antibodies or fusion constructs comprising a “decoy” cytokine receptor coupled to the Fc portion of an IgG molecule. Coupling to Fc increases the half-life and can help with disposal of the target. Another approach is coupling to polyethylene glycol (pegylation), for example, certolizumab pegol used in rheumatoid arthritis (RA) and pegloticase used in treatment-resistant gout.

The starting point for a new therapeutic antibody is either immunization with the target or screening of an antibody library for affinity with the target. The resulting antibody is then engineered to improve its properties, including (1) increasing the affinity of the antibody for its target, (2) replacing animal portions of the antibody with human equivalents to decrease immunogenicity (the generation of antibodies aimed against the therapeutic molecule itself—*antitherapeutic antibodies*—because the patient’s immune system sees these as “foreign”), and (3) enhancing effector functions.

As with small-molecule drugs, the biologic is tested in several activity assays and animal efficacy models, PK properties are assessed, and toxicity potential is studied (see later). Attention is given to developing the stable cell lines that will be used to produce the biologic; scaling up to increasingly large culture systems; establishing processes for purification, quality-testing, and storage; and filling sterile vials or other packaging ready for storage and use in humans.

BOX 49.2 PRECLINICAL CHARACTERIZATION OF A NEW DRUG CANDIDATE

Affinity for target
Activity in enzyme- and cell-based assays
Tissue distribution
Metabolic route, active metabolites*
Predictions of human pharmacokinetics
Identification of pharmacodynamic markers
Kinase (and other off-target) screens*
QT interval liability (effect on hERG, Purkinje system, ECG telemetry)*
Development of translational biomarkers
Efficacy in animal arthritis models
Whole-animal toxicology studies
Genotoxicity screening, carcinogenicity
Phototoxicity
Safety pharmacology
Injection tolerability (subcutaneous biologics)
Stability testing

*For small molecules.

Biologic versus small-molecule drugs

Intracellular molecules are not an easy target for protein biologics because they require specialized delivery systems to move across lipid bilayers. On the other hand, protein-protein interactions over a large surface area are difficult to disrupt with a small-molecule drug and favor a biologic approach.

Although small molecules offer the convenience of oral dosing, in recent years both rheumatologists and patients have gained comfort with biologics. Most patients find injectable drugs an acceptable alternative, particularly if the injection is convenient (e.g., subcutaneous, self-administered, and performed using an “automatic” prefilled injection device), dosing is relatively infrequent, and severe injection-site reactions do not occur.

In addition, because of the high specificity of antibody-antigen interactions, therapeutic antibodies are much less likely than small molecules to have off-target activity, and biologics have more predictable PK properties.

Preclinical safety testing

During *toxicology* studies the drug is given to animals in progressively higher doses to establish the exposures associated with damage to key organs, to determine whether the effects are reversible, and to establish a *no observed adverse effect level* that will guide *first into human* doses and dose escalation schedules in phase 1 clinical trials. In general these studies are done in two species (often rat and dog) for small molecules, and are of sufficient duration to at least match the intended duration of the initial human studies. Because the high specificity of biologics limits their cross-species reactivity, toxicology studies may be done in primates such as the cynomolgus monkey. Innovations such as “lab-on-a-chip” methods may eventually replace some *in vivo* testing.⁵

The final preclinical studies done before the new drug is tested in human subjects (sometimes called *regulatory* or *IND-enabling* studies, where *IND* stands for “investigational new drug”) are performed using *good laboratory practice* standards and drug material prepared according to *good manufacturing practice* (a set of principles to ensure quality practices).

Safety pharmacology studies focus on potential adverse effects on the cardiovascular, respiratory, and central nervous systems. Other preclinical studies are summarized in Box 49.2.

Efficacy models

Preclinical studies include assessment of efficacy in animal models and the exposures needed to produce beneficial effects. Preclinical models of autoimmune disease are notoriously poor at predicting efficacy in the corresponding human disease. Autoimmune diseases in such models are of acute onset, artificially induced rather than spontaneous, occur in animals with a homogenous genetic background and environment, and have a cytokine and cellular pathogenesis that only partly reproduces that seen in the human disease. Nevertheless, such models are valuable for studying the relationship between PK markers and pharmacodynamic (PD) markers (measures of the drug’s activity on downstream pathways) and for devising translational biomarkers.

CLINICAL DEVELOPMENT

Study design

All studies involving human subjects must comply to ethical standards (see Chapter 27). Key aspects include the principle that the patients entering a clinical trial should have tried established standard-of-care therapies with either inadequate response or unacceptable tolerability/safety outcomes or, depending on how inadequate the response was, should continue standard-of-care treatment as stable *background therapy*.

The protocol should also include “escape routes,” so that a patient who does not show adequate response within a defined period of time has access to alternatives, preferably without having to exit the study completely.

The clinical trial protocol describes the study’s scientific rationale, known properties of the drug, objectives and endpoints, inclusion and exclusion criteria, limitations on concomitant use of other medications, study procedures, safety information, clinical trial materials, ethical aspects, and plans for data analysis, including statistical methods. Efficacy endpoints vary according to the indication. In early development, objectives involving PK, PD, and biologic markers feature strongly. In phase 3 trials, key aspects of study design are confirmed in advance with regulatory authorities.

Once the trial has started, any modifications need careful consideration to avoid undermining the credibility of the study’s findings. Investigators should deviate from the protocol only when it is essential for patient safety. Any changes in a protocol are made with a formal *protocol amendment*, which requires review by the institutional review board or ethics committee.

The approach to analyzing the key data—the *statistical analysis plan*—is finalized in advance of unlocking the study database. The methods for handling *missing data* (e.g., when a patient leaves the study early because of drug-related adverse events or lack of efficacy) and *multiple endpoints* should be specified in advance to avoid biases.^{6,7}

The strategic goal(s) of a study from the sponsoring company’s perspective may differ from the stated objectives as described in the protocol. Typically there is a focus on gathering enough key information for decision-making regarding the continued development of the compound according to *go/no-go criteria* that were agreed upon in advance of the study.

Reduction of confounders

Comorbid medical conditions and use of other medications may cloud the interpretation of adverse effects. As much as possible, concomitant medications are kept constant for the duration of the study. For example, changes in background therapy, including prednisone and methotrexate (MTX) dose, usually are very restricted during a clinical trial of a new biologic drug for RA. An exception is that certain study designs have protocol-specified dose reductions, for example a lupus trial aiming to test the steroid-sparing ability of the new drug.

The negative consequence of the desire for a “clean” study is that the populations studied in clinical trials are not representative of the population that is eventually given the drug in clinical practice—they are often healthier, take fewer medications, and are more homogenous.

Patient enrichment

Enrichment is the use of certain patient characteristics to increase recruitment of patients most likely to show a treatment effect or, conversely, to exclude patients who are less likely to show an effect. Enrichment may rely on various characteristics, including patient phenotype, history, treatment responses, serologic parameters, other “routine” laboratory criteria, or radiologic findings, or it may involve a specialized biomarker.

There may be a specific scientific rationale for enrichment (e.g., seropositivity in the case of a B-cell mechanism) or simply the desire to make the population as homogenous as possible (less variability equals a smaller sample size equals a faster, cheaper study). Enrichment is useful in phase 1 and 2 trials to address particular scientific questions, but additional studies would be needed to evaluate the drug’s efficacy and safety profile in the “general” patient population. Enrichment strategies also make patient recruitment more difficult, a challenge not enjoyed by study sites.

Companion diagnostics

A biomarker or genetic test that has sufficient sensitivity, specificity, and prognostic power for predicting which patients will and will not respond well to the drug and that is technically robust for use in a routine clinical diagnostic laboratory may play a useful role in clinical decision-making. When designed to be used in the prescribing decision the test may be

referred to as a *companion diagnostic*. For drugs with a high cost, high toxicity, slow onset, or slow reversibility, such a predictive marker has clear advantages. Under other circumstances the traditional “try it and see” approach may remain perfectly adequate.

Despite extensive research no practical companion diagnostic has emerged for any rheumatology drug, even for the “low-hanging fruit” of highly targeted biologics with a well-understood mechanism of action. Many reported biomarker associations have not been confirmed by larger studies.⁸ Part of the problem is that in chronic inflammatory diseases like RA, the response to a given therapy is seldom a clear-cut yes or no; shades of gray are typical. The more promising personalized medicine approaches in rheumatology have largely been limited to helping avoid uncommon serious toxicities (e.g., thiopurine methyltransferase activity for azathioprine, presence of HLA-B*5801 for allopurinol).

A further obstacle is timely availability. To be of most commercial benefit to a sponsor, the companion diagnostic should be available when the drug is launched. To enable this, the company needs to start development of the companion diagnostic during the late preclinical stages or (at the very latest) in early clinical development.

Good clinical practice

Drug development is highly regulated. Guidelines exist for general aspects of study design, conduct, and interpretation. A large body of guidance documents is available covering preclinical requirements, efficacy, safety, and statistical topics (e.g., www.ich.org, www.fda.gov).

Good clinical practice (GCP) standards provide an internationally agreed upon framework to ensure that the rights and well-being of study participants are protected and to safeguard future patients by ensuring that the data collected during the study are valid. This is done by maintaining an audit trail for all data and using quality control and quality assurance measures to ensure that all data are factual and accurate.

The sponsoring pharmaceutical company will check the *case report forms* at each study site to ensure that the documentation is complete, that any alterations are accounted for, and that important clinical findings can be verified against source material at the site. This *site monitoring* may be done by the company itself or by a *contract research organization*. The site monitors are often referred to as *clinical research associates*. The clinical research associates and the company’s data managers work with the study sites to address any queries before locking the study database.

These procedures reduce, but do not eliminate, the possibility of sloppy or fraudulent activities by clinical researchers. Site monitoring uncovers a variety of problems, including protocol violations, noncompliance with informed consent procedures, poor drug accountability, poor adverse event reporting, documentation problems (missing signatures, missing or incorrect dates), and—fortunately in only a small minority of cases—the deliberate falsification of data.

The sponsor provides a physician with experience in clinical trials—the *medical monitor*—to act as an liaison with investigators and provide additional information about the drug being tested and study procedures, particularly if safety issues arise.

Operational aspects

Steps involved in a clinical trial are summarized in [Box 49.3](#). There is seldom such a thing as a “quick” development study; a protocol with 12 weeks of drug treatment may actually take 15 to 18 months overall (longer for some indications, depending on recruitment kinetics). Times increase further if more study sites are needed and more countries are involved.

Phase 1

Phase 1 studies include *single rising dose* (SRD; also referred to as *single ascending dose*), *multiple rising dose* (MRD, also referred to as *multiple ascending dose*), PK studies including the effects of food and of drug-drug interactions (DDI), studies to exclude an effect on the electrocardiographic QT interval (an effect of small-molecule drugs that interact with certain cardiac ion channels, which carries a risk of the malignant ventricular arrhythmia *torsades de pointes*), and studies in special populations including elderly, renally impaired, and hepatically impaired patients. First-in-human SRD studies of small-molecule drugs for rheumatologic indications are usually done in healthy volunteers. Certain phase 1 studies (e.g., those addressing DDI) often can be deferred and done in parallel with phase 2 and 3 studies.

Ensuring safety is of paramount importance when a new drug is first given to a human subject. Despite extensive preclinical testing there are many uncertainties. Phase 1 studies of a novel small-molecule drug are generally done in a *clinical pharmacology unit* (CPU). The subjects are

BOX 49.3 OPERATIONAL STEPS IN A CLINICAL TRIAL*

Concept for study/clinical development plan	Site initiation
Consultation with external expert advisors	Patient screening
Study synopsis	Initiation of recruitment (first patient in)
Site feasibility survey	Treatment period
Company management approval (multiple layers)	Planned (and <i>ad hoc</i>) safety reviews
Study protocol	Safety follow-up
Institutional review board/ethics committee	Last patient out
Regulatory submission	Monitoring and addressing of data queries
Central laboratory, laboratory kits	Database lock
Biomarker procedures/processing	Unblinding
Investigator meeting	Primary data “flash” analysis
Drug supply, randomization procedures	Decision on drug’s progression
Site paperwork (e.g., review of staff qualifications)	Exploratory analyses
	Clinical study report preparation
	Regulatory submissions
	Preparation of scientific abstracts, publications

*Steps not necessarily in this sequence; activities are conducted in parallel as much as possible to tighten overall timelines. Terminology and processes vary among companies.

resident in the CPU during the study to allow close clinical monitoring, standardization of diet, and the frequent venipuncture needed for safety, PK, and PD assessments.

SRD and MRD protocols have defined decision points for dose escalation and the declaration of the *maximum tolerated dose* (MTD). Various dose-escalation schedules are possible; a common practice is to escalate in approximately half-log₁₀ intervals, for example, 0.1 mg, 0.3 mg, 1 mg, 3 mg, and so on.

Phase 1 studies of biologics are typically performed in patients, often in academic medical centers. The duration of action of a protein drug is long enough that a clinical or biomarker effect can often be anticipated. The term *proof of mechanism* is sometimes used for an efficacy-related signal—for example, a reduction in levels of key cytokines measured in serum, alteration of a messenger RNA expression profile, or perhaps a trend toward improvement in a clinical endpoint for which the sample size does not provide adequate statistical power. Because of the variability inherent in data from small samples, there is the possibility that the new drug may, by chance, look better (or worse!) than it really is; it is common for promising early-phase efficacy data to become less appealing in subsequent better-powered studies.⁹

The size of the SRD and MRD cohorts varies according to the molecule, the indication, the resources of the sponsor, and any particular safety issues or PK-PD questions highlighted in the preclinical program. For an SRD study there might be between 4 and 8 subjects per dose cohort; for an MRDs study, 6 to 12. Typically, a quarter to a third of the subjects receive placebo.

Depending on the number of dose levels, a typical phase 1 MRD and SRD program will include in the vicinity of 50 to 100 subjects. MRD studies for small-molecule drugs are generally of 1 to 2 weeks’ duration, and those for biologics, 1 to 3 months. It is also common to seek preliminary information on food and drug-drug interaction effects during a small-molecule MRD study. In addition to the drug’s having suitable safety, tolerability, and PK properties, progression to phase 2 is usually contingent on its showing an effect on a PD biomarker which confirms that the drug is having a relevant effect *in vivo*.

Phase 2

Phase 2 study goals generally include establishment of *proof of concept* (PoC) for the drug in treatment of the indication being studied and *dose ranging*. Phase 2 studies are performed in patients. It is now common to combine the phase 2a/PoC and the phase 2/dose-ranging components into a single protocol to accelerate progression through clinical development. This reduces overall phase 2 time and hence speeds the availability of a successful drug to prescribers and patients. It is also in the company’s interests, because a combined protocol lowers overall study costs, and faster progression also increases the time between launch of the drug and expiration of the drug’s patent.

PoC requires a robust effect on a clinical endpoint that leaves no doubt as to the drug’s efficacy. PoC may use the same “regulatory” endpoint(s) as a phase 3 trial, subscales of a recognized instrument (e.g., joint counts), or a novel measure. In a phase 2a study, PoC may be tested using a single

“high” dose of the drug (one or two steps below the MTD) in comparison with placebo. Preclinical data, PK data, and PD data from phase 1 predict the doses to administer in phase 2 using *modeling and simulation* approaches.

Standard-of-care (SoC) medication for RA—for example, analgesics, MTX, folic acid, and prednisone (or equivalent, ≤10 mg daily)—may continue as stable background therapy to first assess the new drug as an “add-on” treatment before testing its ability to replace a SoC component. Initial studies generally enroll patients who have experienced an inadequate response to multiple standard-of-care options. For RA, the patient population showing inadequate response to MTX and the population showing inadequate response to a biologic agent differ in ease of recruitment, likelihood of response, applicability for the new drug when launched, and commercial attractiveness.

Dose ranging

For a dose-ranging phase 2b study, it is usual to examine three or four dose levels. It may also be necessary to compare different dose regimens (e.g., once vs. twice a day for a small-molecule drug, every 2 weeks vs. every 4 weeks for a biologic, necessity for a *loading dose*). Broader ranging may be needed if the agent has a novel mechanism of action or if the relationship between drug exposure and clinical response (the PK-PD-*efficacy* triad) is not well understood.

Typical designs for RA trials have 50 or so patients per study arm (depending on statistical power estimations for the desired effect size) and a 12-week treatment period, with a shorter period possible for PoC (e.g., 4 weeks) with some mechanisms of action.

The ideal outcome of a dose-ranging study is to bracket the desired clinical dose by showing that the next dose down has less efficacy and that the next dose above has no added efficacy and perhaps is associated with poor tolerability or high rates of adverse events. Because phase 3 studies involve larger numbers of subjects and longer study periods (with much greater costs for each dose studied), it is preferred to take fewer regimens into phase 3.

Risk may be reduced by *adaptive study designs* in which expansion to a full dose-ranging protocol is gated on seeing a positive efficacy signal and acceptable safety findings in an initial smaller cohort. Adaptive designs may also be used to fine-tune the number of dose levels and numbers of patients taking each dose, although care must be taken to avoid compromising the integrity of the study (e.g., by unmasking treatment assignments).

Additional studies to better understand the mechanism of action of the drug and to help *differentiate* the drug from competitors are often done during phase 2, either as substudies or as separate clinical trials. Rheumatology examples include synovial biopsy and magnetic resonance imaging studies. Studies involving other immunologic indications (e.g., psoriasis, multiple sclerosis, Crohn disease) may also be initiated in parallel with phase 2 as the start of *life-cycle management* for the drug.

In RA phase 2 or 3 studies, it has also become common to include comparison with an established competitor drug, for example one of the biologic tumor necrosis- α antagonists. In phase 2 these comparisons are generally not double blinded (a complex task if the new drug is an oral small-molecule agent and the comparator an injected biologic) and do not include enough patients for formal statistical testing of the new drug’s possible superiority.

Phase 3

Phase 3 clinical trials are done to confirm the efficacy and safety of the drug for treatment of the desired indication. They are much more costly—in the case of emerging rheumatology drugs, \$50 million to \$100 million or more per study.

If the studies during the earlier phases were done well, the phase 3 program should not yield any unpleasant surprises on the efficacy side. A *phase 3 failure* for the drug (inadequate efficacy, unacceptable safety findings) or for the study (major design or conduct flaws) is a huge waste of resources and may represent the inappropriate exposure of many patients to avoidable risk.

In most instances regulatory authorities require two separate, robust phase 3 trials, both showing efficacy of the drug to a rigorous statistical level, to approve the drug. The two pivotal studies might have nearly identical designs but, for example, be done in different regions of the world or with different background SoC. Two studies are needed in case one single trial has a false-positive outcome. Phase 3 studies are sometimes referred to as *pivotal* or *registration* trials.

Patients completing the main part of a phase 3 study (and some phase 2 studies) may be offered entry into an *open-label extension*, which gives them ongoing access to the drug and allows the collection of long-term safety and maintenance of efficacy data.

The size of the phase 3 program is dictated by (1) the efficacy signal expected (for any given statistical power and *P* value, the larger the effect

the smaller the sample needed), and (2) the size of the safety database required. The guidelines of the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use specify minimum requirements (a total of 1500 patients treated for certain time periods), but the chronicity of rheumatic disease treatments and the likely widespread use of a successful new drug require larger samples. Additional phase 3 studies may be done; for example, a study in which a new RA drug is given on a background of several possible disease-modifying antirheumatic drugs and/or with more liberal (“real-world”) entry criteria.

Additional studies conducted after the submission of the new drug to the regulatory authority (*new drug application* for a small-molecule agent; *biologic license application* for a biologic; *marketing authorization application* in Europe) but before the approval of the drug are usually referred to as *phase 3b* studies.

Postmarketing studies

Postmarketing, or *phase 4*, studies are performed after approval of the drug. These are often done as a condition of approval by the regulatory authority, termed a *postmarketing commitment*. These studies are most often performed to obtain additional safety information; for example, a cardiovascular outcomes study may be required if the possibility of an increase in stroke or myocardial infarction was noted during clinical trials or is suggested by the mechanism of action.

Drug safety

Drugs may elicit adverse effects through many mechanisms. Some are implicit in the mechanism of action; for example, any drug that works by modulating the immune response (except via an autoantigen-specific mechanism) may have an impact on host defense against infection and malignancy. This is central to most emerging drugs targeting RA, systemic lupus erythematosus, and spondyloarthritis.

Whether a host defense defect has significant clinical consequences depends on the magnitude of the impact, the part of the immune system affected, and the presence of redundant mechanisms for coping with the pertinent microbes. For predicting whether issues will arise in humans the preclinical host defense models are even worse than the preclinical arthritis models. Close vigilance is needed during clinical development and the postmarketing period.

Adverse events occurring in clinical trials are graded according to severity by agreed-upon criteria (e.g., Common Terminology Criteria for Adverse Events, with Grade 1 being mild and Grade 5 meaning a fatal outcome). When the adverse events are summarized in study reports they can be classified according to the part of the body involved, usually according to system-organ-class categories. Raw data on the incidence of a particular adverse event can also be translated into plain language. The Council for International Organizations of Medical Sciences has defined events occurring in 1 in 10 subjects or more as “very common”; in between 1 in 10 and 1 in 100 subjects as “common” or “frequent”; in between 1 in 100 and 1 in 1000 as “uncommon” or “infrequent”; in between 1 in 1000 and 1 in 10,000 as “rare”; and in 1 in 10,000 or fewer as “very rare.”

An adverse event occurring during a clinical trial is considered serious (SAE) when certain criteria are met: death results, hospitalization (or prolongation of hospitalization) is required, the effect is life-threatening, permanent disability or damage results (or medical intervention was required to prevent these outcomes), or the effect is medically important in some other way (a potential gray zone). All SAEs must be reported quickly, regardless of whether the investigator and/or the company believes they are related to the drug.

An approximate sense of safety during various stages of drug development comes from the *rule of threes*: a study in which 300 patients receive the active drug should catch an adverse event occurring at least once in 100 subjects exposed to the drug; a study of 3000 patients would be needed to largely rule out events occurring at an underlying incidence of 1 in 1000; and so on. Uncovering the uncommon but serious events relies on *postmarketing surveillance*.

Particular concerns over safety aspects may be managed by an independent *data monitoring committee* or *data safety and monitoring board* (DSMB). DSMBs have access to unblinded data during the trial and so can better assess whether a poor risk-benefit balance is emerging. The DSMB may recommend altering or stopping the trial.

Regulatory aspects

Regulatory agencies are government bodies that safeguard patients’ interests by ensuring that a new drug molecule has suitable efficacy and safety in

treating the proposed indication. This role is performed in the United States by the Food and Drug Administration (FDA) and in the European Union by the Committee for Medicinal Products for Human Use of the European Medicines Agency; there are equivalent agencies in other countries.

Submission for regulatory review is a major landmark in the drug development process and requires months of preparation. Similarly, the regulatory agency needs many months to thoroughly review the data. The expected date for a regulatory decision in the United States is often referred to as the *PDUFA date*, a term derived from the Prescription Drug User Fee Act, which dictates the fees the company must pay for review (just under \$2 million in 2013) in return for having a reasonable expectation of timely review.

Special provisions are available for areas of high unmet need. Designation as an *orphan drug* provides certain financial advantages to the sponsoring pharmaceutical company to encourage companies to target uncommon diseases for which the development of drugs might otherwise be unprofitable or seen as too “difficult.” In general this status is more likely to be granted for disorders that have a tightly defined clinical phenotype or specific diagnostic test. The *breakthrough drug* designation is a relatively new pathway designated by the FDA for highly novel approaches.

When a drug is approved, the regulatory agency and the company agree on specific language (the drug’s *label*, *prescribing information*, *package insert*) that describes the indication(s), dosing and administration, and potential safety issues of which the patient and prescriber need to be aware. Major safety issues—for example, a description of serious infection or malignancy risks with a new RA drug—may be described in a *black box* portion of the package insert and advertising material.

Commercial aspects

The time between starting target validation and beginning the first human studies is 4 to 5 years if all preclinical parts of the process go well (and often they do not), and the clinical steps from phase 1 trials through approval take 7 to 8 years. Committing the resources required needs careful evaluation. Major ingredients include knowledge of the number of patients likely to benefit, the efficacy and safety profile that the drug is likely to deliver, the competitive landscape of existing standard of care and emerging competitors (hence, the likely market share), the price the drug is likely to sell for, and the number of years between the launch of the drug and the expiration of the drug’s patent, which will allow entry of a cheaper *generic* version to the market.

A key tool is the *target product profile* (TPP; [Box 49.4](#)). *Market research* is done to explore the weighting that patients, prescribers, and payers place on the various attributes desired of the new drug. The TPP dictates what the clinical trials need to deliver in terms of safety and efficacy requirements. Typically this is some middle ground between what the company’s commercial functions would ideally want in the drug label and what the research, clinical, operations, and regulatory functions think are realistic expectations. The TPP may define attributes that require the new drug to be either the *first in class* (for a novel mechanism) or *best in class* (where one or more competitors with the same mechanism are ahead, e.g., by offering a more convenient dosing regimen).

Company conduct

As publically traded commercial entities, pharmaceutical companies have the standard fiduciary obligation to maximize the returns to their shareholders; in plain terms, *to make as much money as possible*. Fortunately, the interests of shareholders and patients overlap: good drugs can make the company a lot of money, mediocre drugs do not, and bad drugs or unethical corporate conduct invite large financial losses through lawsuits, fines, and wasted development and commercialization costs.

The many historical sins of the pharmaceutical industry have been documented extensively.¹⁰⁻¹² These include off-label promotion; excessive payments (beyond legitimate fee-for-service honoraria) to *key opinion leaders* in a position to influence prescribing; *post-hoc* changes in study design to produce outcomes favorable to the company; and ghost writing of reviews favorable to the company’s drug. A further issue is failure to disclose clinical trial data that might cast doubt on the efficacy and/or safety of the drug, although a recent analysis found that RA studies did not show any evidence of bias from selective publication of “favorable” data.¹³

The consequences of some of these behaviors are not lost on the industry, including large fines (up to \$3 billion in recent years) for illegal promotional activities and the adverse impact on a company’s reputation. The bright sunlight of full disclosure of any potential conflict of interest (ideally through a centralized disclosures database) may prove a good deterrent against excessive financial payments to prescribers and key opinion leaders.¹⁴

BOX 49.4 TARGET PRODUCT PROFILE***Indication**

For the treatment of moderate to severe rheumatoid arthritis in patients who have shown an inadequate response to one or more disease-modifying antirheumatic drugs

Efficacy

ACR50 40% above placebo rate after 12 weeks of therapy
Clinical improvement apparent within 2 weeks of starting dosing
Inhibition of radiographic progression by $\geq 75\%$
HAQ improvement by >0.5 over placebo, significant quality-of-life improvement

Safety

Well tolerated alongside standard-of-care medications
Safe for long-term use
Monitoring requirements not greater than those for methotrexate
Infections not exceeding background rates by $>2\%$
No serious atypical or opportunistic infections greater than background levels

Dosage and administration†

Once-a-day dosing
Flat dosing (same dose irrespective of body weight)
No dose adjustment for age or for mild-moderate renal or hepatic impairment
No dose adjustment for concomitant administration of commonly used drugs

*An optimistic profile for a fictitious new drug intended for treatment of rheumatoid arthritis. Competitive hurdles are lower for diseases that are less well served by current treatment (e.g., systemic lupus erythematosus). Target product profiles (TPPs) may have variations such as *optimistic*, *base case*, and *minimum* requirements, an alternative version if the quest for a predictive *companion diagnostic* is successful, or include explicit comparisons with known competitors. Early in development the TPP is a generic wish list and will be tempered by reality as data emerge and as the competitive landscape evolves.

†Small-molecule example. The TPP for a new protein biologic might instead specify desired attributes such as subcutaneous dosing, injection site reactions in $<5\%$ of patients and not exceeding grade 2, dosing once a month, patient self-administration, and availability of an autoinjection device at launch.

ACR50, American College of Rheumatology 50% improvement criteria; HAQ, Health Assessment Questionnaire.

Economics of drug development

Even for biologics the cost of manufacturing the drug is usually a small proportion of the high marketed price of a new drug; the majority rests on research and development (R&D) costs. Contemporary estimates cover a wide range, with sums between \$1 billion and \$2 billion at today's prices commonly quoted.¹⁵⁻¹⁷ Analysis of R&D expenditures compared with new drug approvals over a 15-year period showed that the 12 largest pharmaceutical companies had spent between \$3.7 billion and \$11.8 billion to produce each new approved drug.¹⁸ These huge sums are driven not so much by the cost of producing the few successful drugs, but rather by the cost of the many more drugs that fail. Failure at later phases is particularly damaging, because phase 3 expenditures account for up to 90% of overall drug development costs.

Although it is clear that drug development costs are high and growing, and that the pharmaceutical industry's productivity is low and shrinking, the solutions are not so apparent. Suggestions include a focus on maximizing the scientific information obtained in early phases of development to reduce the uncertainties of the more expensive later phases.^{16,19,20}

For the clinical development of new rheumatology drugs, this translates into a bigger emphasis on getting efficacy-oriented readouts in the early steps of drug development. Investigators may expect to see an increasing emphasis on biomarker endpoints, early-phase trials conducted in patients rather than in healthy volunteers, patient enrichment strategies, and adaptive and combination designs that minimize costs and the time to complete studies.

CONCLUSIONS

Patients with rheumatic diseases have benefited from several recently approved drugs. Drug development, the process of bringing a new drug from an initial research idea through to the clinic to help address the unmet medical needs of patients, is a long and expensive process with a high rate of failure at each step. New developments in clinical trial design aim to improve the success of the process.

Nonpharmacologic pain management

■ HAYLEY McBAIN ■ KATHLEEN MULLIGAN ■ STANTON P. NEWMAN

- Pain is determined by a combination of biologic, psychological, and social factors.
- Sixty percent of rheumatology patients report severe pain and irritation.
- Nonpharmacologic interventions include cognitive-behavioral therapy, relaxation therapy, patient education, self-management, and social support interventions.
- These types of interventions aim to change behavior, cognitions, and emotions by targeting the psychosocial processes that are implicated in the perceptions of and response to pain.
- There is good evidence that these interventions can be effective in changing pain, particularly in relation to the cognitions surrounding pain; however, this is predominantly in the short term.
- More research is needed to identify who may benefit from nonpharmacologic interventions.

INTRODUCTION

The traditional biomedical model suggests that pain is a direct result of a confirmed organic dysfunction. Treatments are therefore aimed at alleviating or curing this damage and/or blocking these impulses. It is now widely accepted, however, that associations between physical impairment and pain reporting and disability are modest at best. Purely physiologic explanations have been unable to explain why patients sometimes report pain in the absence of physical damage or why identical conditions can lead to pain that varies greatly in severity, intensity, or quality. In response to the shortcomings of the physiologic model, the gate-control theory of pain¹ and a recent extension, the neuromatrix theory of pain, were developed. These theories incorporate both psychological and physiologic factors and offer a biologic basis for the role of psychological factors in pain. The biopsychosocial model of pain recognizes the role of biology and psychology but also the role of social determinants of pain regardless of what the source of the pain is or whether it is associated with psychopathology. It proposes that environmental factors such as the responses of significant others, cognitive factors such as beliefs about pain, and coping behaviors all influence the experience.

PREVALENCE OF PAIN IN RHEUMATOLOGIC CONDITIONS

Pain is the main symptom for most people with arthritis.² In a study of more than 11,000 individuals with a rheumatic condition, over 60% reported severe pain and irritation. Of these, 45% said the pain limited daily activities, 37% felt that the ability to lead a normal life was affected, and 22% were always in pain.³ A comparison of people with osteoarthritis (OA), rheumatoid arthritis (RA), and fibromyalgia found no difference in reported pain severity between individuals with OA and those with RA, but individuals with fibromyalgia reported significantly greater pain severity.⁴ The impact of pain goes beyond the sensation; it is associated with frequent use of medication and health services,⁵ as well as time off work.⁶ Besides the sensation of pain itself, its widespread influence results in a significant impact on quality of life.

MEASUREMENT OF PAIN

Pain is a personal experience; it is not amenable to direct clinical measurement and therefore must be inferred from subjective pain reports. There are various aspects of pain to measure and many ways to perform this measurement. Pain intensity is most commonly measured via rating scales, many of which are considered to be reliable, valid, and appropriate to clinical practice. Some measures, however, may be best suited to individuals experiencing constant daily pain. There are also composite pain scales that are well validated, including the Arthritis Impact Measurement Scale (AIMS). In addition to measures of intensity there are instruments that assess the impact of pain (e.g., Multidimensional Pain Inventory) and the different ways in which people respond to pain.

The experience and qualities of pain have been captured in the McGill questionnaire, which has shown similarities and differences between individuals with different rheumatic conditions. Those with RA and fibromyalgia both use the description *aching and exhausting* to describe their pain. They differ in that RA patients use the words *stiff* and *moving* most frequently, whereas fibromyalgia patients use the words *nagging* and *hurting*.⁷ Pain quality can also be dependent on the activity in which an individual is engaged because pain at rest tends to be described differently from pain in movement.⁸

PSYCHOLOGICAL FACTORS AND PAIN

It is understandable that chronic pain that persists for months and years influences all aspects of a person's functioning. In longitudinal studies, pain has been found to be predictive of physical⁹ and psychosocial¹⁰ health-related quality of life.

Coping with pain

Coping is the cognitive, behavioral, and emotional strategies people use on a day-to-day basis to help them manage the consequences of their disease and has been found to mediate the relationship between pain and physical disability in RA.¹¹ A review of the psychological aspects of persistent pain by Keefe and colleagues¹² suggests that the psychological and behavioral factors associated with more severe pain include catastrophizing (the tendency to focus on pain and negatively evaluate one's ability to deal with and control it), pain-related fear, helplessness, and avoidant coping. In contrast, lower levels of pain are linked to higher levels of self-efficacy (belief that one has the capacity and confidence to deal with one's pain), a greater perception of control, active coping, readiness to change, and acceptance. In fact there is growing evidence that increasing levels of self-efficacy through psychosocial interventions is related to improved outcomes.¹³ Positive relationships have been found between catastrophizing and severity of pain, tenderness, pain-related disability, and disease activity.¹⁴ Similarly, feelings of helplessness have been positively related to levels of pain¹⁵ and may explain why some patients view pain as inevitable and discontinue treatment as a result of failed coping attempts.

Problems for patients can sometimes arise through excessive attempts to control or avoid pain, and there is a growing recognition of the important role of acceptance in management of pain. Acceptance does not involve trying to control or avoid the pain but being willing to perform valued activities regardless of the pain.

Emotions and pain

A number of factors contribute to the coexistence of depression in a large proportion of patients with rheumatic diseases. First, the prevalence of

rheumatic diseases is higher in women, as are levels of depression.¹⁶ There is also a vast amount of literature demonstrating that the presence of pain not only is associated with depression¹⁷ but appears to predict future depression in people with RA¹⁸ and OA.¹⁹

Feelings of anxiety—in particular, fear of completing tasks that may exacerbate pain—can lead to avoidance of activities and situations that involve movement. Studies suggest that fear of movement and reinjury better predict functional limitations than biologic factors or even pain severity and duration.²⁰

Social support and pain

A considerable amount of research has linked lower perceived social support to poorer health outcomes, including higher mortality.²¹ The stress-buffering hypothesis²² proposes that social support helps to mitigate the adverse effects of a stressor such as a chronic disease by enhancing a person's perceived ability to cope with the demands of the disease and by reducing maladaptive emotional or behavioral responses. Social support has been found to have an indirect effect on pain through the use of specific coping strategies and the effectiveness with which these coping strategies are employed.²³ Social support can have detrimental as well as beneficial effects, however; overly protective or overly critical social support has been linked to increased pain.²⁴

PSYCHOSOCIAL INTERVENTIONS FOR PAIN

Many people with pain do not gain adequate relief from medication,²⁵ and there is increasing recognition of the need to include psychosocial approaches in pain management.

Psychosocial interventions to address pain aim to change behavior, cognitions, and emotions by targeting the psychosocial processes that are implicated in the perceptions of and response to pain. These interventions are often offered after traditional biomedical therapies have failed and increasingly alongside traditional pain interventions. A number of general reviews have been undertaken which reveal that psychosocial interventions for people with rheumatologic conditions can significantly reduce pain and increase self-efficacy in comparison with control conditions, although the overall effect size is often small.^{26,27} Psychosocial interventions have a variety of components, often related to each other and customarily presented in combination. A description of the main types and the underlying principles of these interventions is presented before the evidence is examined.

Cognitive-behavioral therapy

The most widely applied and dominant intervention, cognitive-behavioral therapy (CBT), is based on the premise that cognitive and affective factors influence behavior and aims to alter maladaptive cognitive and behavioral responses to pain. CBT aims to assist patients in understanding that they can manage their pain effectively and then provide them with the skills to do so. There are five primary assumptions that underlie all CBT interventions (Box 50.1).

The four essential components of CBT are education, skills acquisition, cognitive-behavioral rehearsal, and generalization plus maintenance. Education aims to provide a credible rationale for the intervention by engaging the patients and encouraging them to believe that they are able to learn the skills necessary to cope better with their pain. Skills acquisition allows patients to learn these new behaviors and cognitions and practice them in the real world. Patients are encouraged to formulate a problem, define an

achievable goal, and identify strategies to achieve that goal, and are rewarded for successful completion. To ensure generalization and maintenance after the completion of the sessions patients are encouraged to anticipate and plan for future events concerning their pain, recognizing that setbacks will occur and that they now have the techniques that will allow them to overcome these problems.

Acceptance-based interventions

Acceptance-based techniques involve developing an awareness of one's pain without judgment, rather than attempting to control or fight it. Mindfulness-based therapies attempt to teach participants how to be aware of the present moment and disidentify with everyday thoughts through formal meditation exercises. Acceptance and commitment therapy targets ineffective coping strategies by helping patients distance and let go of unhelpful thoughts, beliefs, and memories, and accept pain and fully engage with the here and now.

Relaxation therapy

Relaxation is a widely used component of many psychosocial interventions to address pain and aims to reduce the psychophysiologic arousal frequently associated with pain. It involves breathing steadily and deeply and passively ignoring everyday thoughts and is encouraged as a distraction technique for coping when pain is particularly severe. The various forms of relaxation therapy include progressive muscle relaxation (PMR), biofeedback, meditation, autogenic training, and guided imagery.

Patient education

Patient education refers to a set of planned educational activities designed to reduce pain and its consequences. Pain education activities include topics such as information about the condition, encouragement of feasible activities that promote quality of life, the pacing of activities, coping advice, and information about sources of support. The underlying assumption is that patients who are better informed about their condition, treatment options, and prognosis will be better able to manage their disease and therefore achieve better health.

Self-management

Self-management is in part a combination of CBT and patient education, incorporating the idea of patient empowerment. According to Barlow and colleagues,²⁸ “self management refers to the individual's ability to manage the symptoms, treatment, physical and psychosocial consequences and life style changes inherent in living with a chronic condition.” There is a range of possible components to a self-management intervention, and education is one of these. Other widely adopted techniques include self-monitoring, skills training, challenging of unhelpful behaviors, management of emotions, enhancement of communication skills, social support, promotion of readiness to change, enhancement of self-efficacy, problem solving, and goal setting. Fundamental to self-management is skills training to assist patients in managing their condition. Information is seen as a necessary but not sufficient component.

Self-management interventions can help patients understand how their thoughts can influence their behavior and mood and can allow people to explore different ways of viewing situations. Many different psychological theories have been used to develop self-management interventions (Table 50.1). These models all identify concepts that need to be modified to produce a desired change in behavior. By encouraging the routine use of self-management techniques for a particular aspect of a person's disease, such as pain, the hope is that the individual will translate these techniques to address other aspects of the disease. Despite the evidence base for these theories, a number of intervention studies that claim to use self-management techniques are not explicitly based on any theory.

Social support interventions

Social isolation has been found to impact health; therefore, some interventions have aimed to alter levels of social support. The premise is that having others around giving support can encourage appropriate behaviors, provide emotional support and information, and offer alternative ways of dealing with the condition. This can be achieved by creating new social networks relevant to the needs of the patient, such as self-help or support groups. An alternative is to focus on those people already in the patient's life and develop their skills to provide additional and appropriate support.

BOX 50.1 ASSUMPTIONS OF COGNITIVE-BEHAVIORAL THERAPY

1. An individual's behavior is influenced by his or her belief about the expectations and consequences of the behavior.
2. An individual's thoughts may alter his or her behavior by interacting with emotions and physiologic responses, and, in turn, these thoughts may also be influenced by emotional and physiologic responses.
3. The interactions between an individual's behavior and environmental reactions are reciprocal.
4. Interventions should address the emotional, cognitive, and behavioral dimensions of the problem.
5. Individuals must become active participants in learning adaptive methods of responding to their problems.

TABLE 50.1
Models of behavior change

Self-regulation or common sense model ⁵⁶	- Describes how a patient will come to understand his or her illness and how to develop the coping strategies necessary to manage the patient's disease. - Relies on an individual's ability to monitor his or her own actions and reflect on them and their associated consequences.
Social cognition model based on social cognition theory ^{57,58}	- Implies that changing illness perceptions may lead to changes in relevant self-management behaviors. - Suggests that behavior is directly influenced by goals and self-efficacy expectations and indirectly by self-efficacy, outcome expectations, and sociostructural factors. A majority of the empirical applications of this theory focus on self-efficacy.
Theory of planned behavior ⁵⁹	Suggests that behavior is determined by the strength of a person's intention to perform that behavior and the amount of actual control the person has over performing it.
Stages of change or transtheoretical model ⁶⁰	- Assumes that behavior change involves movement through a sequence of discrete stages. - Holds that different factors influence the different stage transitions and that interventions should be matched to the person's current stage.

EVIDENCE BASE

When the evidence base for these interventions is assembled, a number of limitations need to be acknowledged. Descriptions of the interventions often are not detailed enough to be entirely clear with regard to content. The labeling of interventions can also be confusing; for instance, one intervention might be called CBT and another, patient education or self-management when, in fact, they involve similar components. In addition, interventions may have similar content but may differ significantly in duration and in the way in which they were delivered. These problems are common in attempting to integrate findings from complex interventions and make it difficult not only to group interventions by type and compare them but also to draw distinct conclusions about what makes them effective. An additional important caveat is that some interventions are not aimed primarily at managing pain but measure pain as one of many secondary outcomes.

Nonpharmacologic interventions are delivered over a discrete period and are assessed at various times after intervention. The follow-up to determine efficacy has characteristically occurred immediately after or relatively soon after the intervention has ceased. Whether there are enduring effects of nonpharmacologic interventions has only infrequently been evaluated. For example, a review by Dixon and associates²⁶ found that only 10% of studies assessed the impact of the intervention beyond the immediate posttreatment period. An additional complication is the way in which pain is measured. Because different measures of pain cover different concepts and have different psychometric properties, the measure used, rather than the intervention per se, may influence the final conclusions. Finally, a number of studies have compared an intervention with "standard care." Any conclusion about an intervention's effectiveness requires an explanation of "standard care," because standard care differs vastly in different environments and therefore cannot be considered a constant.

Cognitive-behavioral therapy

In a recent review of psychological interventions for pain management in arthritis, 80% were labeled as CBT,²⁶ and of these only two showed significant effects. General reviews have offered contradictory results regarding CBT and pain. A narrative review by Bradley and colleagues²⁹ concluded that CBT is a well-established treatment for RA pain and is probably efficacious for patients with knee OA. However, the authors of a recent Cochrane review, who applied more restrictive selection criteria for studies, examined the effectiveness of psychological therapies for nonmalignant chronic pain, including a number of rheumatic conditions, and concluded that CBT has

weak effects in improving pain.³⁰ When compared with usual care, CBT had a small but significant effect on pain after treatment, but this effect was not maintained at the 6- or 12-month follow-up.

Key to understanding the impact of CBT is to establish for whom the intervention works and what techniques are related to success. Keefe and Van Horn³¹ attribute the variability in the success of CBT interventions to differences in psychological variables such as self-efficacy, pain coping strategies, and feelings of control, as previously discussed. Similarly, when the mediating and moderating factors that predict therapeutic change in CBT were examined, pretest to posttest treatment changes in pain beliefs, catastrophizing, and self-efficacy for managing pain were found to mediate the effects of CBT.³² Other studies have demonstrated that those who adhere to a CBT program are more likely to show gains—an important point, but often taken for granted.

Although some studies fail to find differences in self-reported pain, changes in other associated pain measures have been reported. When Parker and colleagues³³ compared CBT with an educational intervention and standard care in patients with RA, they found no significant difference in self-reported pain but significant changes in pain-related coping strategies, such as control, at 6 months and 12 months after intervention. In addition, when occupational therapy and a standard-care control condition were compared with CBT, Kraaimaat and colleagues³⁴ found that, for people with RA, CBT resulted in a significant increase in the use of distraction after treatment but no change in other pain-related measures.

The long-term effectiveness of CBT has been extensively debated. When compared with standard care, patient education, and symptom monitoring CBT has been found to significantly improve various aspects of pain; however, these significant changes are not always maintained in the long term. These studies suggest that CBT can have a small effect on pain. However, these interventions result in greater improvements in the cognitive and behavioral aspects of pain, such as pain behavior and pain self-efficacy, than in self-reported measures of intensity. These benefits tend to be found immediately after interventions, and there are mixed findings as to whether they are maintained at long-term follow-up. Overall, the need to examine individual differences to identify in whom these interventions are effective and to determine which variables influence outcome is vital.

Acceptance-based interventions

The ability to be mindful and accepting of pain has been found to be predictive of lower levels of catastrophizing.³⁵ When Zautra and colleagues³⁶ compared a mindfulness-based therapy with conventional CBT and an education-only placebo control condition in people with RA, they did not find any differences between the groups in daily pain scores. However, participants in both intervention groups reported greater increases over time in pain coping self-efficacy compared with the control group. Perceived pain control improved more in the CBT and placebo control groups than in the mindfulness-based therapy group.

A systematic review and meta-analysis of studies using acceptance-based interventions for the treatment of chronic pain found a small but significant effect on pain intensity.³⁷ However, the review included only two studies rated as high quality; therefore, the findings must be treated with caution. Although the reported effect size was similar to that of CBT,³⁰ traditional CBT has been tested more widely. Veehof and colleagues³⁷ concluded that mindfulness-based programs are not superior to CBT but may be a suitable alternative, and they recommended further research to identify characteristics that could be important in deciding whether to refer patients to either CBT or a mindfulness-based program.

Relaxation training

A number of systematic reviews have been published looking at the efficacy of specific relaxation techniques in managing chronic pain. Carroll and Seers³⁸ examined nine randomized controlled trials that reported the use of only a relaxation strategy as an active treatment compared with at least one other active or control treatment in individuals with a variety of conditions. The most common form of relaxation was PMR with audiotapes and regular home practice. There was little evidence, however, to support the effectiveness of relaxation in the relief of chronic pain. The two studies in individuals with rheumatologic conditions reported contradictory results. One in RA found a significant benefit in favor of relaxation in at least one pain outcome, whereas hydrogalvanic baths were found to be more beneficial than relaxation therapy in fibromyalgia patients.

In a more recent systematic review, Kwekkeboom and Gretarsdottir³⁹ included studies in which relaxation training had been used in combination with other interventions, such as guided imagery or CBT. They concluded

that, when results were considered across conditions, a majority of studies showed a significant effect of relaxation on pain as measured before and after intervention. PMR, autogenic training, jaw relaxation, and systematic relaxation, in particular, showed benefit. However, when PMR was compared with exercise therapy and hypnosis, no significant effects on pain were found.

These interventions reveal a somewhat mixed picture in terms of the efficacy of relaxation training for pain management. Those studies that used relaxation techniques in combination with other psychological interventions appeared to show more success than those that used relaxation alone, which suggests that it may be other components of the programs that resulted in significant changes in pain.

Self-management and educational interventions

Self-management interventions have received much attention over the past two decades. The most well-established self-management intervention is the Arthritis Self-Management Program. This 6-week program is open to all people with rheumatic conditions and involves peer-led sessions that include information about arthritis, an overview of self-management principles, exercise, cognitive symptom management, ways of dealing with depression, nutrition, communication with family and health professionals, and contracting. Weekly goal setting is encouraged as a means of practicing the skills taught in class and as a way of increasing self-efficacy. There have been numerous studies looking at the efficacy of this training program in various populations, but results with regard to pain have been variable. For example, an evaluation in the United States that recruited participants through public service announcements reported a significant effect on pain at the 4-month follow-up,⁴⁰ but this finding was not replicated in a U.S. primary care setting.⁴¹ A United Kingdom evaluation of this intervention in people with any type of arthritis found no difference in pain scores between the intervention and control groups; however, the intervention group reported a greater improvement in pain control self-efficacy.⁴² Similar results were found when the intervention was evaluated in a United Kingdom primary care setting in a population with OA of the hip or knee.⁴³

A number of systematic reviews have been undertaken to summarize the effectiveness of both patient education and self-management interventions. The findings are somewhat mixed but in general indicate a small effect of self-management interventions on pain, which is not maintained in the long term.

A systematic review of patient education for adults with RA identified 50 studies from 1966 to 2002 and found only a trend toward significance for the effects of patient education on pain scores at first follow-up and no significant effects at final follow-up.⁴⁴ Sensitivity analysis, however, found that there was much variation in the way in which pain was assessed; moreover, the time frame patients were asked to consider in reporting pain (e.g., over the past day, week, or month) varied significantly. A significant effect for the intervention was found at first follow-up when a visual analogue scale was used to measure pain, but no effect was found when validated measures such as the AIMS were used. No long-term effects were found regardless of the type of measure used, nor were there any significant differences when the results for information provision, counseling, and behavioral treatments were examined separately. A more recent meta-analysis of trials published up to March 2010 found that self-management interventions had a moderate significant effect in reducing pain intensity at 4, 6, and 12 months after intervention.⁴⁵ However, only three studies were included in the meta-analyses for 6-month and 12-month follow-up.

A recent systematic review⁴⁶ sought to assess the efficacy of individual behavior change techniques. The review examined whether self-management interventions that included five behavior change techniques—goal setting, planning, self-monitoring, feedback, and relapse prevention—demonstrated greater efficacy than other psychological interventions. The rationale was that these techniques would be expected to facilitate more effective self-management. Cumulative effect sizes of all studies included in the review showed a significant effect on pain immediately after treatment and at follow-up (ranging from 2 to 14 months). Interventions that used more behavior change techniques did not have a greater effect on pain than other interventions; however, they did have a greater effect on depressive symptoms and anxiety.

In a systematic review to determine the long-term benefits of self-management and identify intervention or participant characteristics that are associated with a beneficial outcome Iverson and colleagues⁴⁷ examined 30 articles. Only 14 studies had follow-ups of 12 months or longer, of which 4 demonstrated a significant effect on pain. Booster sessions had been included in eight studies, of which four had follow-ups of 12 months or longer. Only one of these studies found a positive effect on pain, and this

benefit was maintained at the 12-month follow-up. The authors of the review recommended that studies with demonstrated benefits at 6 to 12 months should seek to extend that follow-up period and include evaluation of cost effectiveness. The characteristics of programs that were beneficial (for any outcome, not necessarily pain) were a duration of at least 6 weeks; use of social cognitive or cognitive-behavioral approaches; inclusion of exercise; use of individualized weekly action plans with review; protocolization with participant handbooks; and use leaders trained in grouped facilitation.

In summary, the short-term effects of these interventions seem to be fairly well established, even though many are not specifically designed to target pain. It should also be noted that in a majority of cases these interventions are provided in addition to standard care; therefore, the effects are always supplementary to the benefits of standard practice. There is much less evidence, however, to suggest that these benefits remain in the long-term. Future research needs to establish how short-term benefits can be maintained.

Social support interventions

A small number of interventions have included components that aim to influence health outcomes in musculoskeletal conditions by manipulating social support. These have often involved adapting cognitive-behavioral interventions, and although they have had limited success in changing levels of pain, beneficial effects have been found in pain and coping self-efficacy. Spouse-assisted coping skills training has been assessed in individuals with OA and chronic back pain. In one study spouse-assisted coping skills training was compared with conventional coping skills training and with spouse-assisted education; patients in the spouse-assisted coping skills training group reported significantly higher levels of self-efficacy for pain compared with those in the educational group, but not compared with patients in the conventional coping skills training group. These results suggest that it was the coping skills training, rather than the addition of spousal support, that had an impact on self-efficacy.¹³ In more recent trials patients with OA and those with chronic lower back pain were found to benefit from the addition of spouse assistance in coping skills training, showing higher posttreatment pain-coping attempts and less rumination about pain at the 12-month follow-up.^{48,49} Alternative approaches include providing social skills training to participants; however, although improvements have been found with regard to fatigue, depression, and perceived support, no effect was found for pain.⁵⁰

To date, there does not appear to be strong evidence for a beneficial effect of social support interventions on pain management. Although the relationship between social support and health outcomes is well documented, direct evidence is still lacking for the psychological mechanisms that might help to explain this link, and this hinders the development of well-informed interventions.

USE OF TELEHEALTH IN PAIN MANAGEMENT

Attending an intervention program that lasts several weeks may not be desirable or practical for many people. In fact, a trial to evaluate the efficacy of the Arthritis Self-Management Program in Australia had to be terminated because of lack of sufficient enrollment. Reasons given included work and family commitments, difficulty in getting to courses, and poor health.⁵¹

Recent developments in telehealth may offer a way to make such programs more accessible. Electronically delivered programs may also have the potential to include more intensive booster sessions than is usually feasible and thus help to enhance maintenance of beneficial effects that currently are seen mainly in the short term. Telehealth may also offer more flexibility in tailoring programs to the needs of the individual. Promising attempts have been made to adapt face-to-face self-management interventions for use in patients with fibromyalgia and RA that suggest significantly greater improvement in pain compared with standard care⁵² and high levels of acceptability.⁵³ Although this field is growing rapidly, reviews have reported on few randomized controlled trials assessing efficacy, and therefore a more extensive evaluation is required.^{54,55}

CONCLUSION

Overall there is evidence that psychologically based interventions can be effective in changing pain, particularly in relation to pain cognitions. The findings tend to be clearer for the short term, and the evidence is less persuasive that these results persist in the longer term. To maintain

improvements after the interventions, special attention needs to be paid to the generalization and maintenance of what has been learned and to the integration of these techniques into everyday life.

There is a lack of research investigating which individuals benefit from different types of interventions and the mechanisms through which these

interventions work. In chronic rheumatic pain, attention needs to be directed to the crucial beliefs and coping strategies that have the capacity to explain the effect of psychological interventions. A valuable approach would be to identify these important psychological factors so that future interventions can be tailored appropriately.

Pharmacogenomics in rheumatology

■ JEFFREY D. GREENBERG ■ BRUCE N. CRONSTEIN

- Pharmacogenomics is the application of genomics to optimize drug design and selection and the course of therapy based on individual patients' genetic profiles, whereas pharmacogenetics refers specifically to elucidation of the roles of individual genetic variations in determining drug response.
- Single nucleotide polymorphisms (SNPs) are single nucleotide variations in the DNA sequence occurring in at least 1% of the population and present in the human genome at a density of 1 per 1000 base pairs or greater. SNPs may be tested individually for direct association with a phenotype or be used as part of a set of markers to identify genomic regions associated with a phenotype and are thus a powerful tool in the field of pharmacogenetics.
- Association studies are population-based studies that test for statistically significant relationships between particular genotypes and phenotypes. Association studies have been used widely in efforts to identify putative genetic risk factors for poor or toxic responses to commonly administered therapies for rheumatologic diseases.
- The impact of pharmacogenetics on clinical medicine is likely to be substantially enhanced in the near future by convergence of the availability of larger, better-characterized patient populations, continued improvements in the speed and cost-effectiveness of high-throughput genotyping technologies, optimization of marker selection for more complete and efficient coverage of the genome, and improved understanding of both target disease etiologies and the mechanisms of action of drugs.

PHARMACOGENOMICS

The rapidly growing field of pharmacogenomics focuses on the application of genomics to optimize drug design and selection and the course of therapy based on individual patients' genetic profiles. Pharmacogenetics, a branch of pharmacogenomics, refers specifically to elucidation of the roles of individual genetic variations in determining drug response. Although the long-term impact of these fields on clinical medicine is uncertain, the principle of particular allelic variants affecting the incidence of lack of efficacy or adverse response to drug therapy has been established for decades.¹⁻³ This chapter provides a brief introduction to pharmacogenetics with a focus on practical considerations for researchers in the design and interpretation of pharmacogenetic studies, as well as a review of the current literature on pharmacogenetics research relevant to rheumatology.

In recent years the availability of detailed sequence data in the wake of the Human Genome Project and the rapid evolution of high-throughput genotyping systems have provided tools that substantially enhance the capabilities of researchers in performing genomics research. Of particular utility in identifying genetic markers for directing therapy has been a rapidly increasing number of single nucleotide polymorphisms (SNPs) identified throughout the genome at a reported frequency of roughly 1 per every 1000 base pairs of DNA or higher. Such information is of value for biomedical research on a number of levels. First, identification of an SNP within a gene of known relevance to a phenotype of interest provides the basis for asking whether an allele of that SNP is associated with the phenotype. This could occur directly, such as through alteration of a gene's regulatory properties (e.g., promoter region, splice site, mRNA stability), or by encoding a change

in an amino acid that affects the structure or function (or both) of the protein. Alternatively, a phenotypic association with an SNP allele could result if the allele is in linkage disequilibrium with (i.e., segregates with) an allele of a second SNP or another genetic variation that confers such an effect. Thus, a single SNP may by itself provide a sufficient basis for uncovering a genotype/phenotype association.

SNPs have also become increasingly useful as genetic markers for use in mapping and genome-wide association studies (GWASs). In such cases the SNP is not being used on an individual basis but rather as one of a set of SNPs distributed across the genome such that alleles of particular SNPs within the set that associate with a phenotype of interest serve to identify the region or regions of the genome in which the gene or genes responsible for the phenotype lie. Within what gene, if any, an SNP is located is not of direct importance when it is used for this purpose but rather the extent to which the SNP set adequately covers the genome. In general, the smaller the average distance between SNP markers across the set, the greater the likelihood that at least one marker will be in sufficient linkage disequilibrium with each contributing allele for the tract to be mapped. An important caveat to this rule is that varying degrees of linkage disequilibrium exist across the genome, which results in "blocks" of sequence and, with them, SNPs that segregate together. Such strings of contiguous SNP genotypes are referred to as haplotypes, and a large-scale effort has been completed in which a human genome "HapMap" has been established to identify the location and size of these blocks of sequence to potentially ease the performance of association studies by reducing the number of markers that need to be genotyped to cover the genome.^{4,5} Still, SNP density remains a critical factor in determining the success of such mapping projects, and as the density of known SNPs across different populations continues to increase, so does researchers' ability to interrogate the genetic components of pharmacogenetic (and other) phenotypes.

Experimental approaches and considerations regarding study design and data interpretation

Drug response presents unique challenges as a phenotype (see later) and often limits the experimental approaches that an investigator may apply to elucidate its genetic basis, but many of the design considerations critical to the success of genetic association studies in general apply to pharmacogenetic studies as well. Briefly, in both cases one must address issues such as the heritability of the phenotype (i.e., fraction of the response phenotype attributable to genetic rather than nongenetic factors), the size and make-up of the sample population, the choice of markers, the accuracy of the genotyping methods used, the accuracy of phenotypic classifications, and the statistical methods applied for data analysis.⁶ These and other factors have an impact on the statistical power achieved in the analysis, which is central to the success of any genetic association study.

The most common approach to testing for an SNP association with a drug response phenotype is through clinic-based association studies in which one asks whether the allele frequency of an SNP of interest is significantly different in a group of patients exhibiting a particular response phenotype relative to a control group that does not or, conversely, whether patients with a particular genotype for an SNP or SNPs have a significantly different incidence of a response phenotype relative to those without it. Such studies are most commonly performed retrospectively such that the chart records of patients given a drug are used to categorize them for a response phenotype, after which allele frequency data for SNPs of interest are determined and appropriate statistical analyses are performed to identify associations. This approach, though pragmatic with regard to time and expense, has a number of weaknesses based in part on the fact that because the objectives of the study were not known at the time of drug treatment, the amount

TABLE 51.1
Tests for association of *MTHFR* SNP alleles and response to MTX

Polymorphism	Reported associations	Lack of associations	Reference
C677T	Increased risk for discontinuing MTX therapy because of adverse events Increased rate of toxicity	Efficacy or toxicity Toxicity Efficacy	Van Ede et al. ¹² Urano ¹³ Kumagai ¹⁷ Berkun ¹⁴ Van Ede ¹²

MTHFR, methylenetetrahydrofolate reductase; *MTX*, methotrexate; *SNP*, single nucleotide polymorphism.

lower doses than did those without them. Kumagai and coworkers¹⁷ reported associations of homozygosity for two alleles of thymidylate synthase with higher MTX dosage and 50% or greater improvement in serum C-reactive protein levels, respectively. Neither Berkun and coworkers¹⁴ nor Kumagai and colleagues¹⁷ found associations between either the *MTHFR* 677 or 1298 genotype and efficacy. Wessels and associates¹⁶ reported that the 1298AA genotype was associated with improved efficacy of MTX. Furthermore, a multigene pharmacogenetic model was developed by Wessels and coworkers¹⁹ that included genes for MTX metabolism and purine and pyrimidine synthesis.

In the case of both MTX efficacy and toxicity there has been an apparent lack of consistency in the identification of associations across studies, particularly with regard to *MTHFR* genotype (Table 51.1). To address these inconsistencies, which may relate to cohort size and statistical power, Fisher and Cronstein²⁰ conducted a meta-analysis of published studies on *MTHFR* SNPs and risk for toxicity. In the meta-analysis the C677T SNP was associated with increased risk for toxicity (odds ratio, 1.71; 95% confidence interval, 1.32 to 2.21). As discussed earlier, a number of factors may contribute to variability, and in this instance, relatively small patient populations and inconsistent phenotyping criteria may be at least partially responsible.

Azathioprine

A number of studies have been conducted on the pharmacogenetic properties of azathioprine, with a primary focus on the role of SNPs in the gene for thiopurine methyltransferase (*TPMT*) in determining susceptibility to toxicity, and the literature in this area has been reviewed elsewhere.^{21,22} Among the studies based on data from rheumatologic use, Black and associates²² reported that 5 of 6 individuals who incurred toxicity out of a cohort of 67 patients receiving azathioprine for rheumatologic disease were heterozygous for mutant *TPMT* alleles. In another study, among a group of patients with RA treated with azathioprine, those experiencing adverse effects showed a significantly decreased level of *TPMT* activity relative to those who did not, and toxicity developed in 7 of 8 patients with “intermediate” *TPMT* activity.²³ Combined with evidence from the many studies on patients with nonrheumatic diseases, these data strongly support the notion that the *TPMT* genotype is a useful predictor of azathioprine-associated toxicity.

Sulfasalazine

It has long been established that the pharmacokinetic properties, efficacy, and toxicity conferred by sulfasalazine therapy are influenced by acetylator phenotype,²⁴ and more recently, the relationships of alleles of the *N*-acetyltransferase 2 (*NAT2*) gene with these phenotypes have become increasingly understood.²⁵ Kumagai and associates²⁶ reported that the *NAT2* genotype is associated with both the pharmacokinetics (sulfapyridine/*N*-acetylsulfapyridine) and efficacy of sulfasalazine treatment in a cohort of patients with RA. Tanaka and colleagues²⁷ found in a group of patients with RA that slow acetylators who lacked the *NAT2**4 allele experienced adverse effects from therapy more often than did fast acetylators who had at least

one *NAT2**4 haplotype. Kita and coworkers²⁸ showed that the differences between *NAT2* genotype groups in the pharmacokinetic profiles of sulfasalazine are enhanced after multiple dosing relative to single dosing. These are among the studies demonstrating the importance of variants of the *NAT2* gene on sulfasalazine outcomes.

Biologic disease-modifying antirheumatic drugs

The vast majority of pharmacogenetic studies of biologic agents have focused on tumor necrosis factor (TNF) antagonists for the treatment of RA. Early studies reported associations in relatively small cohorts. Martinez and colleagues²⁹ reported associations within the major histocompatibility complex with response to infliximab after 3 months of therapy in a cohort of 78 patients with RA. Mugnier and associates³⁰ found that among a group of 59 patients with RA treated with infliximab, those with the TNF- α -308 G/G genotype had better response than did those with the A/A or A/G genotypes. In a study based on a population of 123 patients with RA, the combination of -308 TNF1/TNF1 and -1087 G/G was associated with response to etanercept, whereas a combination of SNPs within the interleukin-1 receptor antagonist and transforming growth factor- β 1 gene was associated with nonresponse.³¹ More recently, larger population studies of TNF pharmacogenetics in patients with RA have been published. Criswell and colleagues³² reported that the combination of two HLA-DRB1 shared-epitope alleles, as well as two extended haplotypes that included the HLA-DRB1 shared-epitope alleles and six SNPs in the lymphotoxin- α (LTA)/TNF region, are associated with response to etanercept. The significance of any of these findings remains unclear in light of the common clinical observation that individuals who do not respond to one anti-TNF biologic agent may respond to a different one. One of the largest cohort studies was reported by Maxwell and colleagues.³³ They examined eight SNPs in the region containing the TNF gene in 1050 patients with RA, including 455 prescribed etanercept and 450 prescribed infliximab. An association between the TNF-308 genotype and change in the 28-Item Disease Activity Score (DAS28) was observed, thus replicating the TNF-308 findings of other investigators. However, a subsequent systematic review and meta-analysis, the largest meta-analysis published to date and involving more than 2800 patients, concluded that the TNF-308 variant is not a predictor of response.³⁴ Studies examining RA risk alleles have identified the *PTPRC* gene, which encodes protein tyrosine phosphatase, receptor type C (also known as CD45), as a predictor of response, which has been replicated.^{35,36} However, a subsequent meta-analysis failed to confirm *PTPRC* as a predictor of response to anti-TNF biologics.³⁷

Finally, recent studies have approached the question by using the unbiased GWAS design to identify genetic predictors of response. A pilot GWAS published by Liu and colleagues³⁸ on a small cohort of patients identified a number of promising candidate SNPs. However, these SNPs failed to be replicated as predictors of response in an independent Spanish RA cohort.³⁹ More recently, a larger GWAS was performed to identify additional candidate SNPs, and replication studies will also be required.⁴⁰

CONCLUSION

The work discussed in this chapter provides some evidence for the notion that the pharmacogenetic properties of antirheumatic drugs are likely to play an important role in the future of rheumatology. Because the majority of this work consists of studies focusing on single-allele associations, these data may, in fact, represent only the beginning of what such studies will ultimately yield. As is the case in complex disease genetics, it is likely that the genetic components of drug response will be found to be conferred by multiple genes. Among the challenges for researchers is the difficulty obtaining patient cohorts of sufficient size so that the number of patients in each genotypic category can provide adequate statistical power for analysis. Resolving these issues will require the implementation of large-scale, prospective association studies. Ultimately, the promise of pharmacogenetics will be fully realized when genetic biomarkers can predict who will be more likely to respond to an individual drug and who may incur a drug-related toxicity (Fig. 51.2).⁴¹

The value of pharmacogenetics research to the field of rheumatology, though promising thus far, is likely to continue to grow as the tools and knowledge available to investigators continue to evolve. As the genotyping and analysis tools, as well as the patient cohort data, required for large-scale, genome-wide studies capable of teasing out alleles with increasingly small effect sizes continue to improve, so will investigators' understanding of the target diseases, as well as the mechanisms of action of drug therapies and their toxicities. The convergence of these data is certain to enhance the

Fig. 51.2 Pharmacogenetics has the potential to identify which patients will benefit from a drug with a robust clinical response and which patients will incur drug-related toxicity. power of pharmacogenetics research and thus the promise of rationally individualizing therapy with the use of genetics in the future of clinical medicine.

Principles of opioid treatment of chronic musculoskeletal pain

■ BILL MCCARBERG ■ CHELSEA J. HODGKISS-HARLOW

- Musculoskeletal pain decreases quality of life and productivity across all ages, but the impact may be underestimated in older patients.
- The use of opioid therapy for chronic pain is controversial, but strategies can be implemented to decrease risk to patients and prescribing physicians while continuing to provide compassionate care for suffering.
- Prescription of short- or long-acting opioids can be individualized to the patient based on dose-response and adverse effects. No single opioid is preferred. Cross-tolerance among opioids varies in individuals and should be taken into account when changing opioids.
- Adverse effects can often be managed effectively. Prophylactic management of constipation is recommended on initiation of long-term opioid therapy.
- Aberrant behavior exists along a continuum. The four A's for monitoring patient outcomes should be evaluated during prescription follow up visits. Various strategies can be implemented to distinguish between and manage aberrant behavior.

PRINCIPLES OF PRESCRIBING

Introduction

Although it is difficult to determine the prevalence of pain, according to the 2010 Institute of Medicine Report *Relieving Pain in America: A Blueprint for Transforming Prevention, Care, Education, and Research*, more than 100 million Americans are burdened with chronic pain.¹ Because pain is a common reason to seek medical attention, prescription analgesics are among the 20 most frequently prescribed therapeutic classes and together account for more than 10% of prescriptions.² In a recent survey, less than half of those with pain reported “a lot” of control over their pain despite receiving medical help, and only one third had complete or a great deal of pain relief.³

Pain has an impact on multiple domains of life, with 40% of pain patients reporting that pain interferes with their enjoyment of life, mood, sleep, and activities.³ In addition to affecting quality of life, pain also interferes with the ability to work. American productivity reported in a 2003 study showed that pain conditions cost employers \$61.2 billion each year.⁴ During the study period the U.S. workforce experienced a mean of 4.6 hours of decreased work productivity because of pain, the most common cause being headache, followed by back pain, arthritis pain, and other musculoskeletal pain.⁴

Nearly 20% of the more than 46,000 individuals surveyed in 15 European countries reported pain levels of at least 5 of 10 on a numeric rating scale (NRS); two thirds had moderate pain (5 to 7 on an NRS), and one third had severe pain (8 to 10).⁵ Over-the-counter medications were used by half: 55% used nonsteroidal antiinflammatory drugs (NSAIDs), and 43% used acetaminophen. The most common prescription analgesics were NSAIDs (44%), and only 5% reported taking strong opioids. Rheumatoid arthritis and osteoarthritis (OA) were found in 42% of the respondents, and just 1% reported that their pain was due to cancer. Primary care physicians treated 70% of the patients; 27% were treated by an orthopedist, 9% by a rheumatologist, and 10% by a neurologist or neurosurgeon.

Pain is even more problematic as patients grow older. With diminished sight and hearing, frequent incontinence, and failing memory, all of which impair function and quality of life, a persistent pain problem can be devastating. Epidemiologic studies of long-term care observed that 45% to 80%

of residents have substantial pain of musculoskeletal origin.⁶ A study of 97 elderly patients in extended care found the most frequently reported sources of pain to be lower back pain (40%), arthritis (24%), previous fractures (14%), and neuropathies (11%).⁷ In 325 patients randomly selected from 10 Los Angeles area nursing homes, arthritis accounted for 70% of the pain complaints.⁸ Musculoskeletal pain includes conditions affecting connective tissue, joints, and related structures and is characterized by tissue inflammation, degradation, or metabolic derangement. OA is the most common rheumatic disease seen in older individuals. More than 80% of people older than 75 years have clinical OA, and more than 80% older than 50 have radiologic evidence of OA.⁹ The pain resulting from rheumatic diseases is often unrecognized and untreated, with the undertreatment rate reported to be as high as 85% in long-term care facilities.¹⁰ Inadequate care results from patient fears and insufficient provider education. Falls are common in this population, and concerns about increasing this risk, diminished cognition, addiction, and other side effects, especially constipation, lead to dismissing pain complaints. Elderly patients can contribute to this problem by fearing to report pain. In one study, more than half of all health symptoms were found to be regularly underreported in our aging population.¹¹

Pain mechanisms

Pain arising from rheumatic diseases often starts as acute, inflammatory pain resulting from tissue injury. A variety of inflammatory chemicals and neurotransmitters are involved in this noxious stimulus. Frequently, the pain is proportional to the severity of tissue injury; when repair occurs, the pain subsides. In chronic rheumatologic conditions, however, tissue injury may be of a very low level, yet pain can be persistent. A poor relationship is often found between structural abnormalities and symptoms. Up to 40% of individuals with grade 3 to 4 OA of the knee have no symptoms, and 10% of patients with severe pain have normal radiographic findings.¹² Psychological factors are often implicated but explain very little of this variance between symptoms and anatomy.¹³ Disorders such as rheumatoid arthritis, OA, degenerative disc disease, and chronic gout are associated with persistent pain and may be characterized by intermittent acute exacerbations related to flares of the underlying pathology or be due to patient activity, changes in barometric pressure, anxiety, or other factors.

It is widely believed that older patients do not experience the same intensity of pain as younger populations do.¹¹ Aging is associated with widespread changes in the nervous system designed to sense pain. Although differences exist, the threshold for pain is more likely to be increased in older people.¹⁴ This decreased pain acuity may place older people at greater risk for injury. However, aging does not appear to be associated with substantive functional changes over much of the pain stimulus-response curve.¹⁵ Increases in pain reported with age may occur when stimuli are intense or persist for longer periods. The presence of sensitized pain fibers is a biologic benefit in the presence of injured tissues. However, peripherally sensitized pain fibers are slower to resolve in older people, thus leading to prolonged pain states not seen in younger populations. The commonly held belief that older people are marginally insensitive to pain is not borne out in the literature. Under circumstances in which pain is likely to persist, older people are especially vulnerable to the negative impact of pain.

Opioid therapy for chronic musculoskeletal pain

Opioid therapy for chronic pain has become increasingly contentious and controversial after more than 20 years of escalating use of these powerful drugs. Prescribing opioids to manage chronic pain has been accompanied by alarming increases in misuse and abuse, fatal overdoses, and diversion.¹⁶ There has been a call for action by the federal government, including

voluntary education recommendations on the use of long-acting opioids as part of a risk evaluation and mitigation strategy. Debate about long-term opioid therapy has resulted in a dispute between commitment to compassionate care of suffering patients with chronic pain and adequate response to an epidemic of opioid misuse and abuse.

Strong evidence supporting the use of long-term opioid therapy for patients with chronic pain is lacking. Controlled trials lasting up to 6 months show only modest pain relief versus placebo; whether this efficacy is maintained is unknown.^{17,18} The American Pain Society and the American Academy of Pain Medicine reviewed the literature in 2009 and rated 21 of their 25 recommendations as being based on “low-quality evidence.”¹⁸ Yet it is clear to many practicing providers that in some patients, opioids provide improvement in pain with substantial functional enhancements over alternative therapies.

Given the knowledge gaps and escalating concerns about misuse, abuse, and opioid-related deaths, greater caution and selectivity are needed when prescribing long-term opioid therapy. Until stronger evidence becomes available, clinicians should prescribe cautiously and limit long-term therapy to patients who receive significant benefits. The 1996 consensus statement by the American Pain Society and the American Academy of Pain Medicine¹⁹ on chronic opioid therapy failed to predict the current epidemic of misuse and abuse.¹⁶ The rate of prescription opioid abuse in clinical practice varies from 4% to 26%,²⁰ but misuse is not rare. Rates as high as 26% were found for purposeful oversedation, 39% for unilaterally increasing doses, 20% for coadministering alcohol to relieve pain, and 18% for purposes other than pain.²⁰ As many as 13,000 yearly overdose deaths involve prescription opioids, thus exceeding motor vehicle accidents as the leading cause of death from injury in persons 35 to 54 years of age.²¹

Opioid risks are not limited to addiction and overdose deaths. Side effects, most commonly constipation, can be problematic, especially in an older population. Neuroendocrine dysfunction can result in hypogonadism with infertility, erectile dysfunction, decreased libido, osteoporosis, and mood disturbances.²² Central and obstructive sleep apnea, cardiac rhythm disturbances, immunosuppression, and tooth decay are among the many distressing side effects. Opioid-induced hyperalgesia heightens nociceptive perception paradoxically by making pain sensations worse, not better, and leads to escalating doses, especially when the provider is not aware of this effect.²³

Despite the lack of long-term evidence and risks to the patient and society, patient comfort and quality of life must be taken into account. Lacking adequate alternatives for reducing pain and increasing function, opioid therapy should be considered and in selected patients may be the best option. Even though risk is increased in older patients, the lack of adequate alternatives has led the American Geriatrics Society to recommend that all patients with moderate to severe pain be considered for opioid therapy.²⁴ The medical risks associated with long-term opioid therapy have clearly not been studied adequately, which has led others to conclude that the risk may outweigh the benefits despite the lack of safe alternatives.²⁵

Patient selection for long-term opioid therapy

Selecting patients for long-term opioid analgesic therapy requires careful assessment of the pain, including the medical history and physical examination, as well as the characteristics of the patient and disease. When opioid treatment is warranted, a treatment plan should state objectives that will be used to determine treatment success, such as pain relief and improved physical and psychosocial function, as well as whether other treatments are planned to improve outcomes.²⁶ Such treatments may include nonopioid analgesics such as NSAIDs or adjuvant therapies, including duloxetine, which may allow a lower opioid dose.²⁷ Nonpharmacologic modalities such as psychological and physical strategies, when appropriate and available, should also be considered as additional treatment options.²⁸ Most state medical boards have adopted wholly or in part the recommendations for prescribing opioids outlined by the policy from the Federation of State Medical Boards. This policy includes the following:

- Patient evaluation—includes the history and physical examination to arrive at a diagnosis, psychological evaluation, and risk for addiction.
- Treatment plan—includes alternatives to opioids and expected functional outcomes.
- Informed consent and treatment agreement—informed consent may differ from the treatment agreement; however, both may be included in one form. Informed consent and treatment agreements may be written, signed documents or verbal agreements, but it must be documented in the medical record that the patient understands the risks, benefits, and alternatives to opioid therapy and appreciates what is

expected during treatment (i.e., one pharmacy, refill interval, urine drug testing, and other requirements).

- Periodic review—varies by state.
- Referral—some states require consultation (e.g., Washington when more than 120 mg of morphine equivalent is used), whereas other states suggest referral when appropriate.
- Documentation—inadequate documentation is the most frequent area in which providers are found deficient.
- Compliance with relevant law—for example, prescribing methadone or Suboxone for addiction without the appropriate license.

Assessing pain

Assessment of pain should include the type and quality of pain, source, intensity, location, duration and time course, pain affect, and effects on lifestyle and functional status. Pain intensity can be measured with tools such as an NRS, verbal rating scale, visual analog scale, and the faces of pain scale.²⁹

Assessing risk

Long-term opioid management requires assessment of risk for misuse and abuse. Several tools have been validated, including the Opioid Risk Tool (ORT) and the Screener and Opioid Assessment for Patients with Pain (SOAPP). The five-question ORT predicts which patients may be at risk for opioid-related aberrant behavior once treatment is initiated (Table 52.1).³⁰ The SOAPP is another brief, self-administered screening instrument used to assess the suitability of patients for long-term opioid analgesic therapy.³¹ Tools such as the ORT or SOAPP should be used by clinicians when considering initiating opioid analgesic therapy for a chronic pain problem or for a patient being treated with opioids for an acute pain problem that is becoming chronic and long-term opioid therapy is an option.

Informed consent

Patients must understand the risks and benefits of the long-term use of opioid therapy. The physician can consider the use of a written agreement outlining the treatment plan, expectations, and responsibilities of the patient and physician; this is particularly important if the patient is at high risk for medication abuse. A written and signed form may be required in some states. The procedures or actions that will be taken should problems arise must be explained.³² A sample informed consent is available at http://www.painknowledge.org/physiciantools/Opioid_Informed/Opioid%20Informed%20Consent%20Formatted_1_23_2008.pdf.

Opioid selection

Selecting an opioid requires knowledge of the patient's pain intensity, age, medical comorbid conditions, previous experience with opioids,

drug-specific differences (interpatient variability and drug-drug interactions), and available formulations and cost. Intermittent pain that is related to activity may be better treated with short-acting schedule 3 opioids combined with acetaminophen or ibuprofen taken as needed. No single opioid is preferred. In recent years, recognition of the large individual variation in response to different opioids warrants searching for the best opioid for individual patients. Therapeutic failure with one drug may be followed by remarkable success with another.

For persistent pain, a long-acting agent is recommended to control baseline pain, supplemented by a short-acting agent for breakthrough pain. Since all opioids have similar efficacy, personal experience, the patient's previous exposure to pain medication and experience (including efficacy and adverse effects), and cost should guide therapy. Most short-acting opioids require a dosing interval of 4 to 6 hours, whereas long-acting agents are effective for 8 to 72 hours.

When initiating an opioid trial in an opioid-naïve patient, short-acting agents are preferred with the dose individualized to the patient. Start at the lowest dose likely to be effective and increase gradually until the desired pain relief and functional improvements have been achieved with tolerable side effects.³³ Dose increases of 30% to 50% are safe and usually large enough to observe a meaningful change in effect.³⁴ If the pain is severe and the patient is not predisposed to opioid toxicity, a higher increment—up to 100% of the existing dose—may be safe and effective.³⁴

Another method for increasing doses is to calculate the amount of breakthrough medication used in a 24-hour period and convert this amount to the fixed daily dose schedule. Single-entity opioids (e.g., oxycodone) can be titrated without a ceiling dose, whereas opioid combinations are limited by the amount of acetaminophen or ibuprofen that they contain. Side effects may limit dose titration and thus prompt rotation to another opioid that may not have the same adverse effects. After a stable dose is achieved with a short-acting opioid, it may be converted to a long-acting opioid if a simplified regimen is desired or to optimize adherence.

Methadone has a long half-life and therefore requires care during titration. Because of availability and cost, methadone is a popular long-acting analgesic. Its elimination half-life can be quite variable among individuals and ranges from about 12 hours to almost a week. Methadone may also prolong the QT interval, particularly at higher doses.³⁵ In addition, methadone has been responsible for a disproportionate number of unintentional deaths because of provider inexperience and too rapid dose adjustments. Always wait 3 to 5 days before titrating the dose of methadone if pain control is inadequate.

Pharmaceutically long-acting opioids include sustained-release (SR) preparations of short-acting or immediate-release opioids (e.g., morphine, oxycodone, fentanyl, hydromorphone, oxymorphone). Some of the SR opioids can also be initiated in opioid-naïve patients, although not all have been systematically evaluated as an initial agent. For the oral SR opioid formulations, patients should be advised to swallow the tablet whole and not to break, crush, or chew the tablet because this can result in rapid release of high doses of the opioid and overdose.

Managing side effects

Side effects are common, with constipation being the most frequent adverse effect reported. Sedation, nausea and vomiting, pruritus, sweating, dry mouth, and weakness also frequently occur. All these adverse effects, however, may be missed unless the patient is specifically questioned.

Constipation may contribute to abdominal pain, distention, nausea, and anorexia and may progress to bowel obstruction. Constipation should be anticipated and treated prophylactically. Numerous types of laxatives are available, including bulk-forming agents, lubricants, osmotic agents, surfactants, contact cathartics, prokinetic drugs, a chloride channel activator, and opioid antagonists.³⁶ The conventional first-line approach is a combination of docusate, a stool softener (surfactant), and a cathartic agent (either senna or bisacodyl). Most patients respond to this therapy. For patients who do not, a trial of an osmotic agent, such as lactulose, or a lavage agent, polyethylene glycol, might be considered.

When traditional laxatives are not effective, methylnaltrexone administered subcutaneously can also be considered.³⁷ Patients with refractory constipation may be considered for a trial of a prokinetic drug (metoclopramide). Lubiprostone, a unique chloride channel activator, may also be tried for refractory constipation.

Individualize therapy

Because of variability in efficacy, side effects, and tolerance profiles,²⁰⁻²³ some patients may respond better to one opioid than to another with enhanced analgesia and side effects.³⁸ Itching, for example, may occur with one opioid (common with morphine) and not another. Opioid requirements may vary

TABLE 52.2
Dosing and conversion chart for opioid analgesics

Drug	Route	Equianalgesic dose (mg)	Duration (hr)	Plasma half-life (hr)
Morphine	IM	10	4	2-3.5
	PO	30	4	4
Codeine	IM	130	4	3
	PO	300	4	
Oxycodone	IM	—		
	PO	30	3-4	4
Hydromorphone	IM	1.5	4	2-3
	PO	7.5	4	
Meperidine	IM	75	3-4	2
	PO	300	3-4	Normeperidine
Methadone	IM	10*	6-8†	12-24
	PO	20*	6-8†	20-200
Fentanyl	IV	0.1		
Hydrocodone	IM	—		
	PO	30	3-4	4

*The equianalgesic dose of methadone with respect to other opioids is extremely variable with chronic dosing. The conversion factor from oral morphine to oral methadone may range from 4:1 to 14:1.

†Central nervous system depression is a risk with repeated use, and accumulation may occur in the elderly or persons with impaired renal function with regular dosing. Monitor for patient variability in the duration of efficacy.

IM, intramuscularly; IV, intravenously; PO, orally.

Adapted from Foley KM. The treatment of cancer pain. *N Engl J Med* 1985;313:84-95.

because of differences in μ -opioid receptors and necessitate higher or lower doses. Opioid switching is common since it is not currently possible to predict which individual will respond to any one opioid.³⁹ The availability of a wide variety of opioids allows clinicians to better match a drug to the patient.

Incomplete cross-tolerance

When switching from one opioid to another, conversion tables are frequently used (Table 52.2). However, the new opioid may be less efficacious and result in less analgesia, increased pain, and occasionally withdrawal symptoms. In others the effect is exaggerated, with patients being overly sedated and rarely leading to respiratory depression and death. It is assumed that if a patient is tolerant of one opioid, that patient will be tolerant of another opioid, but the principle of incomplete cross-tolerance illustrates that μ -receptor variability makes tolerance difficult to predict.⁴⁰

Clinicians have long used the principle of incomplete cross-tolerance among analgesics whereby highly tolerant patients are rotated to treatment with a different drug to regain analgesic sensitivity. When switching opioids in an opioid-tolerant patient, it is recommended that calculation of the equianalgesic dose be based on the predicted equivalent dose in conversion tables and then the calculated dose lowered by 25% to 50% to account for incomplete cross-tolerance. Safety is maintained with this method, but at the expense of efficacy. Breakthrough medication must often be used until adequate analgesia is achieved.

Drug-drug interactions

Since most drugs are metabolized through the liver via the hepatic cytochrome P-450 system, care must be taken when using opioids.³⁴ The isoenzyme 2D6 converts codeine and hydrocodone to the active drugs morphine and hydromorphone, respectively. Methadone, oxycodone, and tramadol are also metabolized through 2D6. Fentanyl and buprenorphine are metabolized by 3A4. Concomitant treatment with drugs that inhibit or induce CYP450 enzymes can affect the level of these opioids and their metabolites, thus changing their analgesic efficacy or side effect profile and causing possible opioid overdose or acute withdrawal.^{41,42} Many potential interactions can produce clinically relevant effects (Table 52.3).

The importance of hepatic metabolism is shown in the conversion of prodrugs such as codeine or hydrocodone. Up to 10% of the population lack the enzyme pathway needed for converting these compounds to their active agent and have a poor analgesic response.⁴²

Morphine, hydromorphone, and oxymorphone are metabolized chiefly through conjugation reactions with uridine diphosphate glucuronyl transferase enzymes (glucuronidation). Since they do not use hepatic pathways,

TABLE 52.3

Common inhibitors and inducers of CYP450 enzymes

Enzyme	Opioid substrate	Inhibitor	Inducer
CYP2D6	Codeine, hydrocodone, methadone, oxycodone, tramadol	Citalopram (weak), desipramine, fluoxetine, olanzapine (weak), paroxetine, sertraline, venlafaxine (weak), quinidine	Carbamazepine, phenobarbital, phenytoin
CYP3A4	Fentanyl, meperidine, buprenorphine	Dextromethorphan, fluoxetine (weak), paroxetine (weak), sertraline, venlafaxine, azole antifungals, macrolide antibiotics, nefazodone	Carbamazepine, dexamethasone, erythromycin, modafinil, phenobarbital, phenytoin, rifampin

inhibition/induction or genetic polymorphisms should have little effect on activation or clearance of these drugs.

Periodic review

Follow-up for patients taking opioids long-term depends on the stability of the medical condition and the patient. Required follow-up intervals may be mandated by state medical board pain acts and vary across the United States. Regular monitoring should assess *analgesic* response, *activity* level or functional outcomes, *adverse* effects of the opioid treatment, and *aberrant* behavior observed during the follow-up period.⁴³ Box 52.1 lists these four A's to remind clinicians that a successful outcome in pain therapy involves more than a pain score. Stabilization or improvement of psychosocial functioning and sleep, tolerable side effects, optimization of physical functioning, and absence of aberrant behavior should also be considered.⁴⁴

Referral to an expert in pain management may be mandated by state pain acts to ensure adequate evaluation and management of chronic pain patients, especially when troublesome behavior surfaces with opioid therapy. A pain specialist or pain center should be involved whenever clinicians have exceeded their expertise in any specific area of opioid-related pain management. This may include the dose of opioids prescribed, the patient's ability to adhere to the prescribed regimen, an inability to achieve adequate pain control despite increasing the dose of opioids or switching to different opioids, unresolved troublesome side effects, or unresolved issues of substance misuse or abuse.⁴⁵ Special attention should be given to patients identified during risk assessment to be at high risk for medication misuse and abuse.

Differentiating aberrant drug-related behavior

Aberrant behavior exists in a continuum, with no type being absolutely predictive of addiction (Box 52.2).⁴⁶ The differential diagnosis of aberrant drug-related behavior includes addiction, undertreatment of pain, and psychological distress, but criminal intent and diversion should also be considered. It is important that clinicians distinguish between addiction with physical dependence, tolerance, and pseudoaddiction. The four A's include evaluation of aberrant behavior since monitoring and prescribing of the opioid should change when this behavior surfaces. More frequent follow-up, smaller amounts of medication, urine drug testing, access to a prescription-monitoring program (PMP), and referral to addiction specialists are among the changes to be considered when aberrant behavior is noted.

Psychological factors that may lead to aberrant behavior include anxiety, depression, bipolar disorder, personality disorder, or changes in cognitive state because of the treatment regimen.⁴⁷

Addiction is a primary chronic neurobiologic disease with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behavior that includes one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.

Physical dependence is a state of adaptation that is manifested by a withdrawal syndrome produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, or administration of an antagonist.

Tolerance is a state of adaptation in which exposure to a drug induces changes that result in a diminution in one or more of the drug's effects over time.

Finally, pseudoaddiction is a drug-seeking behavior resulting from inadequate opioid dosing. Patients may seek alternative sources or increased doses.⁴⁸

Urine drug testing

Urine drug testing has become commonplace in pain practices and is recommended by state medical boards. Whom to test and how often to screen

BOX 52.1 THE FOUR A'S OF OPIOID MONITORING

Analgesia
Activities of daily living
Adverse effects
Aberrant drug-related behavior

BOX 52.2 EXAMPLES OF ABERRANT DRUG-RELATED BEHAVIOR

Less indicative of aberrance

Drug hoarding during periods of reduced symptoms
 Acquisition of similar drugs from other medical sources
 Aggressive complaining about the need for higher doses
 Unapproved use of the drug to treat another symptom
 Unsanctioned dose escalation one or two times
 Reporting psychic effects not intended by the clinician
 Requesting specific drugs

More indicative of aberrance

Prescription forgery
 Concurrent abuse of related illicit drugs
 Recurrent loss of prescriptions
 Selling prescription drugs
 Multiple unsanctioned dose escalations
 Stealing or borrowing another patient's drugs
 Obtaining prescription drugs from nonmedical sources

From Reference 46.

vary by providers and patient risk factors. Higher-risk patients as identified by the ORT or SOAPP or patients demonstrating aberrant behavior or deviation from the opioid agreement should be screened more often. Some pain practices screen patients at the first visit and at random intervals throughout their care. The point-of-care urine test done in the office uses an immunoassay and has known false negatives and false positives. Gas chromatography/mass spectrometry (GC/MS) done at reference laboratories can identify multiple drugs and specific drug types and has far fewer inaccurate results. GC/MS provides higher specificity for compounds, but none of the current testing can identify the quantity of the opioid taken, especially when opioids are used chronically.

A positive urine drug test is defined as follows:

- Absence of a prescribed drug
- Presence of an unprescribed scheduled drug or an illicit substance

Cross-reactivity, false positives, and false negatives can confound the results of the urine screen and skew the results; for example,⁴⁹

- Several quinolone antibiotics can potentially produce false-positive results for opioids by immunoassay but are correctly identified by GC/MS.
- Codeine and heroin are metabolized to morphine. Patients taking codeine should have morphine identified in their urine.
- Hydrocodone metabolizes to hydromorphone, and both compounds should show up in the urine.

- Cannabinoids may show up in the urine of patients taking NSAIDs, Marinol, and pantoprazole. Bystander exposure to marijuana will not result in a positive test for cannabinoids.
- Opioids may be present in the urine of patients ingesting poppy seeds, chlorpromazine, and dextromethorphan.
- Amphetamines may be identified in patients taking ephedrine, trazedone, bupropion, and Vicks Vapor Spray.

When interpreting the results of urine drug tests, consider the possibility of errors and patient variability, and therefore repeat the testing if indicated.

Prescription-monitoring programs

Most states have PMPs that allow providers access to all pharmacies within a state giving an identified patient scheduled medication (Fig. e52.1). Similar to urine drug testing, PMPs can be useful when questions arise about patient's aberrant behavior. Many pain practices check the state PMP at the first referral and at each visit.

Nonsteroidal antiinflammatory drugs

■ CARLO PATRONO

- Nonsteroidal antiinflammatory drugs (NSAIDs) continue to provide “background” antiinflammatory therapy for rheumatic diseases.
- Variability in response to NSAIDs is seen in terms of both antiinflammatory activity and adverse events.
- Newer NSAIDs with selective inhibition of cyclooxygenase-2 (COX-2) are associated with a lower incidence of gastrointestinal adverse events.
- The vast majority of COX-2 inhibitors, regardless of selectivity, are associated with increased risk for myocardial infarction.

INTRODUCTION

Nonsteroidal antiinflammatory drugs (NSAIDs) constitute a chemically heterogeneous group of compounds that provide symptomatic relief of pain and inflammation associated with a variety of human disorders, including the rheumatic diseases. Their shared therapeutic actions (i.e., analgesic, antiinflammatory, and antipyretic) are usually accompanied by mechanism-based adverse effects that can, at least in part, be attenuated as a function of their individual pharmacokinetic or pharmacodynamic properties, or both.¹ The main chemical classes of NSAIDs are detailed in Table 53.1.

MECHANISM OF ACTION

The best characterized mechanism of action of NSAIDs is inhibition of the cyclooxygenase (COX) activity of prostaglandin (PG) H synthase 1 and 2 (PGHS-1 and PGHS-2, also referred to as COX-1 and COX-2) (Fig. 53.1). Given the role that prostanoids such as PGE₂, PGI₂, and thromboxane A₂ (TXA₂) play in the local modulation of many important cellular functions, this mechanism of action is probably sufficient to explain the clinical effects of NSAIDs.

Administration of PGE₂ and PGI₂ causes erythema, an increase in local blood flow, and in concert with other inflammatory mediators (e.g., bradykinin), hyperalgesia and enhanced vascular permeability.¹ Moreover, PGE₂ interacting with its EP₃ receptor can produce fever. Thus, prostanoids reproduce the main signs and symptoms of the inflammatory response. Because of the redundancy of mediators of this response, it is not surprising that NSAIDs exert only a moderate antiinflammatory effect, are effective only against pain of low to moderate intensity, and reduce fever but do not interfere with the physiologic control of body temperature.¹

Production of the prostanoids involved in these responses appears to be triggered by the immediate availability of constitutively expressed COX-1 and to be amplified and sustained by the local induction of COX-2 in response to inflammatory and mitogenic stimuli.² Although the analgesic, antiinflammatory, and antipyretic actions of traditional NSAIDs are largely reproduced by coxibs (a class of selective inhibitors of COX-2), this finding does not exclude a potential role for COX-1 in mediating, at least in some individuals, the PG-dependent contribution to pain and inflammation.³

The ability of acetaminophen to inhibit COX-1 and COX-2 is importantly conditioned by the peroxide tone of the local environment.⁴ This may explain, at least in part, the clinical observation that although sharing the analgesic and antipyretic effects of NSAIDs, acetaminophen has relatively poor antiinflammatory activity at conventional doses. High concentrations

of leukocyte-derived peroxides accumulate at sites of inflammation and may impair the ability of acetaminophen to inhibit COX-2.⁴ However, circulating plasma levels of the drug following the administration of 1000 mg systemically inhibit COX-2 activity to a comparable degree as traditional NSAIDs and coxibs.⁵

CYCLOOXYGENASE ISOZYME SELECTIVITY

PGG/H synthase is found in two isoforms that are products of two different genes (see Fig. 53.1): PGHS-1, or COX-1, which is expressed constitutively in all cells but is inducible under appropriate conditions, and PGHS-2, or COX-2, which is inducible in response to inflammatory, mitogenic, or hemodynamic stimuli but is also constitutively expressed in some tissues, such as certain areas of the human kidney and brain.^{2,3}

The COX isozyme selectivity of a particular drug is critically dependent on its concentration.³ One can describe the selectivity profile of different COX-2 inhibitors by plotting the drug concentrations required to inhibit the activity of human platelet COX-1 against those required to inhibit human monocyte COX-2 by 50% (IC₅₀) in whole blood assays (Fig. 53.2). This type of analysis establishes two important facts:

1. COX-2 selectivity is a continuous variable that does not justify a dichotomous definition of selective and nonselective inhibitors.
2. Substantial overlap in COX-2 selectivity is found with some coxibs (e.g., celecoxib) and some traditional NSAIDs (e.g., nimesulide and diclofenac).³

One can pragmatically characterize three levels of COX-2 selectivity in terms of the probability of sparing COX-1 at therapeutic plasma levels: low (e.g., acetaminophen), intermediate (e.g., celecoxib, nimesulide, and diclofenac), and high (e.g., rofecoxib, etoricoxib, and lumiracoxib).

PHARMACOKINETICS AND DRUG INTERACTIONS

The vast majority of NSAIDs are organic acids that are well absorbed orally, highly bound (i.e., 95% to 99%) to plasma proteins, metabolized by the liver, and excreted by either glomerular filtration or tubular secretion.¹ Most NSAIDs are rapidly and completely absorbed from the gastrointestinal tract, with peak plasma concentrations occurring within 1 to 4 hours. Food tends to delay absorption without affecting peak plasma levels.¹

NSAIDs tend to accumulate at sites of inflammation, thus potentially confounding the relationship between plasma concentrations and duration of the antiinflammatory or analgesic effect. Some pharmacokinetic features of representative NSAIDs are listed in Table 53.1. Several traditional NSAIDs (e.g., ibuprofen and diclofenac) are characterized by very short half-lives (1 to 2 hours), which would hardly justify thrice- or twice-daily regimens of administration. To prolong the duration of action, some of these older NSAIDs (e.g., diclofenac) have been developed with formulations and doses that achieve high-grade and sustained inhibition of COX-2 in the systemic circulation. Although this may improve clinical efficacy, it may also influence COX-2-dependent untoward effects, such as cardiovascular toxicity (see later). Some NSAIDs, such as sulindac and nabumetone, are administered as inactive prodrugs that are converted in the large intestine or the liver (or both) into the active metabolites that are largely responsible for COX inhibition. Some of these redox reactions are reversible. Enterohepatic recycling of indomethacin and sulindac can occur and contribute to sustained plasma concentrations of the NSAID.¹

TABLE 53.1

Main chemical classes and representative nonsteroidal antiinflammatory drugs along with selected pharmacokinetic and pharmacodynamic properties

Chemical class and representative drugs	Time to peak plasma concentration (hr)	Half-life (hr)	Dosing regimen	Cyclooxygenase isozyme selectivity
Salicylates				
Aspirin	0.5-1	0.3	q4-6h	COX-1 = COX-2

The pharmacokinetics of most NSAIDs can be affected to some extent by liver disease, renal disease, or old age. NSAIDs should either be avoided or be used with caution under these circumstances and the daily dose adjusted accordingly.¹

NSAIDs can modify the pharmacokinetics or pharmacodynamics of other drugs given concurrently and result in clinically important drug interactions (Table 53.2). Pharmacokinetic interactions are related to the capacity of NSAIDs to modify the metabolism (e.g., warfarin), protein binding (e.g., sulfonylurea hypoglycemic drugs), or renal excretion (e.g., lithium) of other drugs, which often results in supratherapeutic plasma levels of the latter; the dosage of such agents may require adjustment to prevent toxicity.¹

A pharmacodynamic interaction may occur between most NSAIDs and several classes of antihypertensive drugs. Reduced production of the vasodilator PGI₂ in the renal cortex and of the natriuretic PGE₂ in the medulla, as a consequence of COX-2 inhibition, results in vasoconstriction and sodium and water retention, which in turn tend to elevate blood pressure regardless of the mechanism of action of the antihypertensive drugs.¹ This pharmacodynamic interaction has been described with most traditional NSAIDs (including acetaminophen)⁶ and coxibs³ but not with low-dose aspirin.⁷

The pharmacokinetic interaction between NSAIDs and warfarin that may result in supratherapeutic plasma concentrations of the latter because of its displacement from plasma protein binding and reduced metabolism is

further complicated by the fact that NSAIDs may transiently inhibit platelet function in some patients and thus amplify the impairment of primary hemostasis induced by warfarin.

Some NSAIDs favoring COX-1 versus COX-2 inhibition, such as ibuprofen and naproxen (see Fig. 53.2), may interfere with the antiplatelet effect of low-dose aspirin by competing with acetylsalicylic acid for a common docking site (arginine 120) within the COX-1 channel.⁸ Previous occupancy of Arg-120 by an NSAID will prevent aspirin from acetylating a serine residue (Ser-529) just below the COX catalytic site of the enzyme, which forms the basis of the unique mechanism of action of aspirin that results in permanent inactivation of platelet COX-1.⁷ Drugs favoring COX-2 versus COX-1 inhibition, such as acetaminophen and diclofenac, do not interfere with the pharmacodynamic effect of low-dose aspirin, similar to celecoxib and rofecoxib (Fig. 53.3).⁸ Based on current analysis of the data available, the Food and Drug Administration has issued a statement informing patients and health care professionals that ibuprofen can interfere with the antiplatelet effect of low-dose aspirin (81 mg/day), thus potentially rendering aspirin less effective when used for cardioprotection and stroke prevention (available at www.fda.gov/cder/drug/infopage/ibuprofen/default.htm).

Low-dose aspirin can cause upper gastrointestinal bleeding.⁷ In two large outcome trials, subgroup analyses suggested that aspirin may attenuate the gastrointestinal safety of coxibs as compared with traditional NSAIDs.^{9,10}

Fig. 53.1 Arachidonic acid, a 20-carbon fatty acid containing four double bonds, is liberated from the sn2 position in membrane phospholipids by phospholipases, which are activated by diverse stimuli. Arachidonic acid is converted by cytosolic prostaglandin (PG) G/H synthases, which have both cyclooxygenase (COX) and hydroperoxidase activity, to the unstable intermediate PGH_2 . The synthases are colloquially termed cyclooxygenases and exist in two forms: COX-1 and COX-2. PGH_2 is converted by tissue-specific isomerases to multiple prostanoids. These bioactive lipids activate specific cell membrane receptors of the superfamily of G protein-coupled receptors. TX, thromboxane.

Fig. 53.2 The concentrations of various cyclooxygenase-2 (COX-2) inhibitors needed to inhibit the activity of platelet COX-1 and monocyte COX-2 by 50% (IC_{50}) are plotted on the abscissa and ordinate scales, respectively. The solid line describes equipotent inhibition of both COX-1 and COX-2. Symbols to the left of this line denote greater inhibition of COX-1 than COX-2. Symbols to the right of this line indicate progressively greater inhibition of COX-2 than COX-1, that is, increasing degrees of COX-2 selectivity. 6-MNA denotes 6-methoxy-2-naphthylacetic acid, the active metabolite of nabumetone. (Data from FitzGerald GA, Patrono C. *The coxibs, selective inhibitors of cyclooxygenase-2*. *N Engl J Med* 2001;345:433-42; and García Rodríguez LA, Tacconelli S, Patrignani P. Role of dose potency in the prediction of risk of myocardial infarction associated with nonsteroidal anti-inflammatory drugs in the general population. *J Am Coll Cardiol* 2008;52:1628-36.)

CLINICAL EFFICACY

NSAIDs are most widely used as analgesic and antiinflammatory agents for the management of osteoarthritis, rheumatoid arthritis, and ankylosing spondylitis. The clinical efficacy of these drugs is related to symptomatic relief of the pain and inflammation associated with these musculoskeletal disorders. However, NSAIDs are not disease-modifying agents and do not arrest progression of tissue injury.¹

The results of phase 3 efficacy studies in osteoarthritis, rheumatoid arthritis, and various models of acute pain have established that the analgesic and antiinflammatory effects of coxibs are indistinguishable from those of several NSAID comparators (often, diclofenac, ibuprofen, or naproxen), consistent with similar COX-2 inhibition at comparable doses.³

Potential variables contributing to different COX-2-dependent effects include the daily dose of the inhibitor, which determines the extent of COX-2 inhibition; the half-life and dosing interval of the inhibitor, which determines the duration of COX-2 inhibition; and the patient's substrate inasmuch as the importance of COX-2-dependent prostanoids is likely to vary in different clinical settings.³

NSAIDs are particularly effective when inflammation has caused sensitization of pain receptors to normally painless mechanical or chemical stimuli. The pain that accompanies inflammation and tissue injury probably results from local stimulation of pain fibers and enhanced pain sensitivity (hyperalgesia), in part as a consequence of the increased excitability of central neurons in the spinal cord.¹

The choice among different NSAIDs for the treatment of osteoarthritis and rheumatoid arthritis remains largely empirical and based on efficacy, but it may be guided rationally by safety considerations (see later). Substantial differences in clinical response have been noted among individuals treated with the same NSAID and within an individual treated with different NSAIDs. This may be related to the quite substantial interindividual variability in the pharmacokinetic and pharmacodynamic relationship, as noted earlier.

If the patient does not achieve therapeutic benefit from a 2-week trial with one particular NSAID, another should be tried. Combination therapy with more than one NSAID has no scientific rationale, and the risk for adverse effects is at least additive.

ADVERSE EFFECTS

Shared adverse effects of NSAID therapy are listed in Table 53.3. The list includes minor symptomatic disturbances, as well as serious and life-threatening complications. The latter represent a growing safety concern, particularly in elderly patients, because age is associated with an increased probability of serious adverse reactions to NSAIDs.¹¹ When assessing clinically relevant outcomes of NSAID therapy, one should consider the variable incidence rate of these outcomes in the general population (Table 53.4). No placebo-controlled trials of adequate size and duration have been performed with traditional NSAIDs to reliably evaluate the excess of these serious outcomes attributable to NSAID therapy. Thus, we have to rely almost entirely on the results of observational studies that give a quantitative assessment of the risk for important outcomes (see Table 53.4). If the associations found in epidemiologic studies were causal, approximately 300 upper gastrointestinal bleeding or perforation events, a similar number of hospitalizations for congestive heart failure and nonfatal myocardial infarction, 5 acute liver injuries, and 4 to 8 hospitalizations for acute renal failure per 100,000 persons per year would be attributable to NSAID therapy.¹¹

Gastrointestinal

The most common symptoms associated with NSAID therapy are gastrointestinal, including nausea, abdominal pain, and diarrhea. These symptoms do not necessarily reflect NSAID-induced mucosal lesions or ulcers because they occur commonly in placebo-treated patients. Gastrointestinal ulcers, as assessed by endoscopy, are detectable in 30% to 50% of NSAID-treated patients and develop in a dose- and time-dependent fashion. However, less than 10% of NSAID-treated patients have symptomatic ulcers, thus emphasizing the poor correlation between upper gastrointestinal symptoms and lesions. Gastrointestinal ulcers may be single or multiple and can be accompanied by gradual blood loss leading to anemia or by life-threatening bleeding. The risk for NSAID-induced ulceration is increased in patients infected with *Helicobacter pylori*, heavy alcohol drinkers, or those taking concomitant low-dose aspirin, clopidogrel, warfarin, or glucocorticoids.¹

Coxibs have been shown to be associated with a lower incidence of endoscopic gastroduodenal ulcers than equally effective doses of traditional

TABLE 53.2

Interactions between nonsteroidal antiinflammatory and other drugs

Drug affected	NSAID implicated	Effect	Approach to management
Oral anticoagulants	Phenylbutazone Oxyphenbutazone Azapropazone	Inhibition of the metabolism of S-warfarin, which increases the anticoagulant effect	Avoid NSAIDs if possible Use careful monitoring when use is unavoidable
Lithium	Probably all NSAIDs	Inhibition of renal excretion of lithium, which increases lithium serum concentrations and the risk for toxicity	Use sulindac or aspirin if an NSAID is unavoidable Closely monitor the lithium concentration and appropriate dose reduction
Oral hypoglycemic agents	Phenylbutazone Oxyphenbutazone Azapropazone	Inhibition of the metabolism of sulfonylurea drugs, which prolongs the half-life and increases the risk for hypoglycemia	Avoid this group of NSAIDs if possible; if not, monitor the blood glucose level closely
Phenytoin	Phenylbutazone Oxyphenbutazone Other NSAIDs	Inhibition of the metabolism of phenytoin, which increases the plasma concentration and risk for toxicity Displacement of phenytoin from plasma protein, which reduces total concentrations for the same unbound (active) concentration	Avoid this group of NSAIDs if possible; if not, intensify therapeutic drug monitoring Avoid aspirin; closely monitor the plasma concentration if another NSAID is used
Methotrexate	Probably all NSAIDs	Reduced clearance of methotrexate (mechanism unclear), which increases the plasma concentration and risk for severe toxicity	This is relevant only to the high-dose methotrexate used in cancer chemotherapy
Sodium valproate	Aspirin	Inhibition of valproate metabolism, which increases the plasma concentration	Avoid aspirin; closely monitor the plasma concentration if another NSAID is used
Digoxin	All NSAIDs	Potential reduction in renal function (particularly in the very young and very old), which reduces digoxin clearance and increases its plasma concentration	Avoid NSAIDs if possible; if not, perform frequent checks of the plasma concentration of digoxin and the plasma creatinine level
Aminoglycosides	All NSAIDs	Reduction in renal function in susceptible individuals, which reduces aminoglycoside clearance and increases the plasma concentration	Closely monitor plasma concentration and dose adjustment
Antihypertensive agents: β -blockers, diuretics, ACE inhibitors, vasodilators	Indomethacin Other NSAIDs	Reduction in hypotensive effect, probably related to inhibition of renal prostaglandin synthesis (which produces salt and water retention) and vascular prostaglandin synthesis (which produces increased vasoconstriction)	Avoid all NSAIDs in patients with cardiac failure; monitor for clinical signs of fluid retention
Diuretics	Indomethacin Other NSAIDs	Reduction in natriuretic and diuretic effects; may exacerbate congestive cardiac failure	Avoid NSAIDs in patients with cardiac failure; monitor for clinical signs of fluid retention
Anticoagulants	All NSAIDs	Gastrointestinal tract mucosal damage, together with inhibition of platelet aggregation, which increases the risk for gastrointestinal bleeding in patients taking anticoagulants	Avoid all NSAIDs if possible
Low-dose aspirin	Ibuprofen and naproxen	Prevention of irreversible inactivation of platelet COX-1	Use NSAIDs with some degree of COX-2 selectivity

ACE, angiotensin-converting enzyme; COX, cyclooxygenase; NSAID, nonsteroidal antiinflammatory drug.

NSAIDs.³ Prophylaxis with a proton pump inhibitor, such as omeprazole, or a prostaglandin analogue, such as misoprostol, has been shown to reduce the risk for NSAID-induced, endoscopically verified ulcers.¹

Upper gastrointestinal complications (bleeding, perforation, and obstruction) occur in 1% to 2% of NSAID-treated patients. The mortality rate associated with hospitalization for major gastrointestinal events is 5% to 6% in recent studies.¹² Mortality rates associated with upper or lower gastrointestinal complications secondary to NSAIDs are similar.¹² The major risk factors for upper gastrointestinal bleeding are older age and a previous history of gastrointestinal disorders (Fig. 53.4).¹¹ Male gender, cigarette smoking, and heavy alcohol intake increase this risk by less than twofold, as do oral glucocorticoids. Oral anticoagulants, thienopyridines, and low-dose aspirin increase the risk for NSAID-induced bleeding complications by twofold to threefold.¹¹ The excess of these complications attributable to traditional NSAIDs has been estimated to range between 3 and 30 events per 1000 patients treated per year,¹¹ depending on the absence or presence of risk factors.

Because of the low event rate of ulcer complications, very large sample sizes or prolonged drug exposure is needed to detect differences between drugs. Four large (8000 to 35,000 patients) randomized trials of 6 to 18 months' duration have compared the gastrointestinal safety of coxibs with that of traditional NSAIDs: CLASS (Celecoxib Long-term Arthritis Safety Study—celecoxib versus ibuprofen and diclofenac),⁹ VIGOR¹³ (Vioxx Gastrointestinal Outcomes Research—rofecoxib versus naproxen), TARGET¹⁰ (Therapeutic Arthritis Research and Gastrointestinal Event Trial—lumiracoxib versus ibuprofen and naproxen), and MEDAL¹⁴ (Multinational Etoricoxib and Diclofenac Arthritis Long-term program—etoricoxib versus diclofenac). The main characteristics of the approximately 69,000 patients enrolled in these studies are detailed in Table 53.5. The rate of ulcer

complications associated with traditional NSAIDs in these trials ranged between 5 and 15 per 1000. As can be appreciated in Figure 53.4, these values are consistent with the rates of upper gastrointestinal complications predicted by analysis of epidemiologic data for a comparable low-risk population (i.e., women aged 60 with a largely negative previous gastrointestinal history).¹¹ Both in VIGOR and TARGET, a highly selective COX-2 inhibitor was associated with a statistically significant 50% to 66% relative risk reduction in ulcer complications as compared with naproxen or ibuprofen.^{10,13} Based on recently completed meta-analyses of individual participant data from all the available randomized trials, the risk for upper gastrointestinal complications was almost twice as high for naproxen as for ibuprofen and diclofenac (Coxib and traditional NSAID Trialists' [CNT] Collaboration).¹⁵ The gastrointestinal risks of all the NSAIDs were evident within the first 6 months of treatment.¹⁵

When contrasting the options of using a highly selective COX-2 inhibitor or a traditional NSAID plus a proton pump inhibitor, the following points should be borne in mind:

1. In contrast to coxibs, proton pump inhibitors have not been demonstrated to reduce the risk for NSAID-induced ulcer complications in adequately sized randomized trials.
2. Whereas coxibs have been shown to reduce the risk for both upper and lower gastrointestinal events, proton pump inhibitors would not be expected to protect against the latter.

Finally, it should be emphasized that any COX-2-selective inhibitor may eventually inhibit COX-1 in some patients (because of interindividual variability in pharmacokinetics or pharmacodynamics) and that there may be untoward COX-2-dependent effects (e.g., interference in ulcer healing) that are shared by all COX-2 inhibitors regardless of selectivity.³

Fig. 53.3 Ibuprofen, celecoxib, and the antiplatelet effect of low-dose aspirin in patients with osteoarthritis and ischemic heart disease. Platelet cyclooxygenase-1 activity, as assessed by measurement of serum thromboxane (TX)B₂ levels, in aspirin-treated patients randomized to receive placebo (a and d), ibuprofen (600 mg 3 times daily [TID]) (b and e), or celecoxib (200 mg twice daily [BID]) (c and f) for 7 consecutive days. Median values (and interquartile range) are depicted in panels a, b, and c. Individual data points (and median values, as depicted by horizontal bars) are reported in panels d, e, and f with values of serum TXB₂ expressed as percentage of baseline (i.e., prior to randomized treatment). (Data from Renda G, Tacconelli S, Capone ML, et al. Celecoxib, ibuprofen, and the antiplatelet effect of aspirin in patients with osteoarthritis and ischemic heart disease. *Clin Pharmacol Ther* 2006;80:264-74.)

Fig. 53.4 Upper gastrointestinal complication (UGIC) rates were estimated in women according to age and the presence or absence of a history of such complications and regular use of traditional nonsteroidal antiinflammatory drugs (NSAIDs). The solid lines connecting each pair of green (control) and blue (NSAIDs) symbols depict the excess risk for complications related to NSAID therapy. (Data from Hernández-Díaz S, García Rodríguez LA. Epidemiologic assessment of the safety of conventional nonsteroidal anti-inflammatory drugs. *Am J Med* 2001;110[Suppl]:20S-27S; and unpublished results of S. Hernández-Díaz and L.A. García Rodríguez.)

Cardiovascular

Persistent (throughout the dosing interval and beyond) and virtually complete (i.e., greater than 97%) inhibition of platelet COX-1 by any commercially available dose of aspirin is associated with a 20% to 30% reduction in major vascular events (nonfatal myocardial infarction, nonfatal stroke, or vascular death), as demonstrated by more than 50 placebo-controlled randomized trials involving approximately 100,000 subjects at high cardiovascular risk.⁷ Traditional NSAIDs have long been thought to pose no cardiovascular hazard or to be somewhat cardioprotective, even in the absence of any randomized study supporting this widely held assumption. Because of their reversible mechanism of action in inhibiting platelet COX-1 and their short half-lives (see Table 53.1), most traditional NSAIDs inhibit TXA₂-dependent platelet activation only transiently and incompletely in the vast majority of users (Fig. 53.5). A notable exception is provided by naproxen, which has been shown to inhibit TXA₂ biosynthesis *in vivo* to the same extent as low-dose aspirin when administered regularly at 500 mg twice daily,¹⁶ consistent with its relative COX-1 selectivity and longer half-life than other commonly used NSAIDs.

Three placebo-controlled trials have revealed a twofold to threefold increased risk for vascular events in approximately 6000 patients treated short-term (10 days) with valdecoxib¹⁷ or long-term (up to 3 years) with celecoxib¹⁸ or rofecoxib,¹⁹ both with and without concomitant aspirin treatment. These findings are consistent with a mechanism-based cardiovascular hazard for the coxib class.²⁰ In fact, coxibs depress the biosynthesis of vascular PGI₂, an important modulator of blood pressure and thromboresistance, without concomitant inhibition of platelet activation.^{21,22} A meta-analysis of tabular data from 138 randomized trials of five different coxibs involving approximately 145,000 patients has revealed that in placebo comparisons, allocation to a coxib was associated with a 42%

increased incidence of vascular events with no statistically significant heterogeneity among the different coxibs.²³ This excess risk for vascular events was derived primarily from a twofold increased risk for myocardial infarction. Overall, no significant difference was found in the incidence of vascular events between a coxib and any traditional NSAID, but there was evidence of significant heterogeneity between naproxen and the other traditional NSAIDs (largely represented by ibuprofen and diclofenac).²³ The apparent lack of a significant difference in the rate of vascular events between patients treated with any coxib and those treated with other NSAIDs, as

reported in this meta-analysis, is confirmed by the cardiovascular findings of the MEDAL program.²⁴ In this prespecified pooled analysis of data from three trials that included 34,701 patients with osteoarthritis or rheumatoid arthritis treated on average for 18 months, the hazard ratio for thrombotic cardiovascular events was 0.95 (95% confidence interval, 0.81 to 1.11) for etoricoxib versus diclofenac. The results of an updated meta-analysis

REVERSIBLE VERSUS IRREVERSIBLE INHIBITION OF PLATELET COX-1 ACTIVITY BY ASPIRIN AND A TRADITIONAL NSAID

Fig. 53.5 The average time course of inhibition of serum thromboxane B₂ (TXB₂), an *ex-vivo* index of platelet cyclooxygenase-1 (COX-1) activity, is depicted over a 24-hour period after the administration of low-dose aspirin once daily and a traditional NSAID with a short half-life given every 8 hours. The inset depicts interindividual variability in the relationship between NSAID plasma levels plotted on the abscissa log scale and the corresponding level of inhibition of platelet COX-1 plotted on the ordinate. Only 2 of 44 individual blood samples achieved greater than 95% inhibition of platelet COX-1 activity.

■ **TABLE 53.4**

Incidence rates of major events possibly caused by traditional nonsteroidal antiinflammatory drugs as assessed in observational studies in the general population

Event	Incidence rate per 1000 patient-years	Increased risk	Hospitalizations per 100,000 NSAID users
Heart failure	2-4	2-fold	300
Myocardial infarction	1-4	2-fold	300
Upper gastrointestinal bleeding	0.6-1.7	4-fold	300
Acute renal failure	0.02-0.08	2-4-fold	4-8
Acute liver injury	0.02-0.04	2-fold	5

of coxib trials²⁵ that included the MEDAL²⁴ and ADAPT²⁶ (Alzheimer's Disease Anti-inflammatory Prevention Trial) studies confirmed the statistical heterogeneity between coxib versus naproxen and coxib versus other NSAID comparisons.

Given the nonlinear relationship between inhibition of platelet COX-1 activity and inhibition of platelet activation *in vivo*,²⁷ it is perhaps not surprising that the cardiovascular safety profiles of coxibs and some traditional NSAIDs appear similar in that they both fail to inhibit platelet activation adequately irrespective of their COX-2 selectivity.

Thus, coxibs and some traditional NSAIDs moderately increase the risk for vascular events, particularly myocardial infarction, but there remains considerable uncertainty about the magnitude of this hazard for particular drug regimens and patient subgroups. Early appearance,²⁸ dose dependence,²⁹ and slow dissipation²⁸ of risk appear to be important features of COX-2-related cardiotoxicity.

Use of NSAIDs can lead to the development of congestive heart failure in susceptible individuals.³⁰ Based on epidemiologic studies,^{11,30} current users of NSAIDs are estimated to have a twofold increased risk of hospitalization for congestive heart failure. The effect is greater in patients with preexisting heart disease. The risk appears to be dose dependent and somewhat higher during the first month of therapy.^{11,30}

A meta-analysis of individual participant data from all the available coxib and NSAID randomized trials¹⁵ has largely confirmed the main features of cardiovascular toxicity associated with COX-2 inhibition (Fig. 53.6). Moreover, coxibs, diclofenac and ibuprofen increased the risk for vascular death by 50% to 60% but had no significant effect on nonvascular causes of death.¹⁵

Renal

Both traditional NSAIDs and coxibs have been associated with renal and renovascular adverse events, consistent with the important role of constitutively expressed COX-2 in sustaining the physiologic production of vasodilator and natriuretic prostanoids in the human kidney.^{1,3}

COX-2 inhibitors have little effect on renal function or blood pressure control in healthy subjects. However, in patients with chronic glomerular disease, hepatic cirrhosis, congestive heart failure, hypovolemia, and other states of activation of the sympathoadrenal or renin-angiotensin systems, maintenance of renal blood flow and the glomerular filtration rate is critically dependent on renal PG synthesis.^{1,3}

Some studies evaluating the risk for chronic renal conditions (e.g., analgesic nephropathy) associated with traditional NSAIDs, including aspirin and acetaminophen, have found that NSAID users have a twofold increased

risk for these conditions. The risk increases with age and is related to dose and duration of NSAID intake.^{11,31}

The incidence rate of hospitalization for acute renal failure among non-users is approximately 2 per 100,000 persons per year. Current users of NSAIDs are estimated to experience a twofold to fourfold increased risk of hospitalization for acute renal failure. The risk is dose dependent and is considerably higher during the first month of therapy.^{11,31}

Other risk factors for acute renal failure are male gender, older age, cardiovascular comorbidity, renal diseases, concomitant use of other nephrotoxic drugs, and recent hospitalization for disorders other than renal disease.^{11,31}

Respiratory

Asthma is most common with salicylates but may be precipitated or exacerbated by other NSAIDs. Symptoms may be mild or severe, and fatal attacks of bronchospasm have been precipitated by a single dose of an NSAID. If aspirin-sensitive asthmatic patients require an NSAID, a low dose should be administered in a controlled environment equipped with facilities to reverse bronchospasm. Pulmonary alveolitis has also been reported with NSAID therapy and, though rare, should be considered when an illness suggestive of pulmonary infection but failing to respond to antibiotic therapy develops in a patient taking an NSAID. Limited data suggest that coxibs can be used safely in asthmatics.³² Nonacetylated salicylates are often used in this situation.

Hepatic

Both traditional NSAIDs and coxibs are among the most common agents associated with drug-induced liver injury ranging from asymptomatic elevations in aminotransferase levels to serious liver injury with acute hepatic failure. Observational studies have reported nimesulide, sulindac, and diclofenac to be associated with the highest risk for liver injury, and the only risk factor consistently identified in these analyses is the concomitant use of other hepatotoxic drugs.^{11,33} In the MEDAL program,²⁴ diclofenac caused elevations in aminotransferase levels more frequently than etoricoxib did, generally during the first 4 to 6 months of therapy, although clinical liver events requiring hospitalization were relatively rare.

Nimesulide has been withdrawn in Finland and Spain because of hepatotoxicity, but it continues to be prescribed in Italy and Portugal with some restrictions.

RATIONAL SELECTION OF NONSTEROIDAL ANTIINFLAMMATORY DRUG THERAPY

Patients with rheumatic disease have quite substantial interindividual variability in their response to NSAIDs. The therapeutic challenge in each case is to find the right NSAID and appropriate dosing regimen that provide an acceptable level of pain relief while minimizing the risk for serious adverse events.

Because gastrointestinal and cardiovascular adverse events contribute the largest share of NSAID-induced toxicity, careful consideration should be given to assessment of risk factors for these complications in the individual patient.

Because of the nature of serious complications that could be caused or prevented by one particular NSAID versus another, patients' values and preferences should be considered in the choice of NSAID therapy. Moreover, patients should be adequately informed about the balance of benefits and risks to obtain their cooperation in achieving the following goals:

- Minimizing the level and duration of drug exposure
- Avoiding concomitant over-the-counter analgesic medications
- Complying with prescribed dietary, physical, and pharmacologic means in managing modifiable cardiovascular risk factors (i.e., cigarette smoking and higher than optimal blood pressure, cholesterol, and body weight).

In light of the heterogeneous regulatory and marketing environment in the United States versus Europe (Table 53.6), uniform treatment recommendations are difficult to make. Although some preferred treatment options have been suggested^{32,34-36} according to the level of cardiovascular and gastrointestinal risk, these are based largely on expert opinion. However, the most recent analyses based on individual patient data suggest that the cardiovascular and gastrointestinal risks associated with both coxibs and traditional NSAID regimens are approximately proportional to the estimated baseline risk for each type of event and can therefore be predicted.¹⁵

Fig. 53.6 Rate ratios (RRs) are for comparisons of a traditional nonsteroidal antiinflammatory drug (tNSAID) versus placebo, calculated indirectly from ratio of RRs for a coxib versus placebo and RRs for a coxib versus tNSAID, each of which is shown in the vertical columns. Event rate ratios, with 95% confidence intervals, are indicated by a diamond; rate ratios for individual tNSAIDs, with 99% confidence intervals, are indicated by a square and horizontal line. Diamonds to the right of the solid line indicate hazard with tNSAIDs versus placebo, but this is conventionally significant only if the diamond does not overlap the solid line. (Adapted from Coxib and traditional NSAID trialists' (CNT) secretariat, unpublished. Courtesy Dr. Colin Baigent.)

TABLE 53.6

Elements of a heterogeneous and evolving scenario concerning nonsteroidal antiinflammatory drug therapy in the United States and Europe

Variable	USA	Europe
Marketing scenario	Celecoxib is the only marketed coxib. Some COX-2-selective NSAIDs (e.g., nimesulide) are not marketed.	Celecoxib and etoricoxib are marketed in most countries. Nimesulide is marketed in some countries but has been withdrawn in others.
Regulatory scenario	Etoricoxib and lumiracoxib have not been approved. Celecoxib is not contraindicated in patients at high cardiovascular risk. Cardiovascular warning has been placed on celecoxib and all traditional NSAIDs except aspirin.	Celecoxib, etoricoxib, and diclofenac are contraindicated in patients at high cardiovascular risk. No such contraindication is on the label of other traditional NSAIDs.

COX, cyclooxygenase; NSAIDs, nonsteroidal antiinflammatory drugs.

Systemic glucocorticoids
in rheumatology

■ KENNETH G. SAAG ■ FRANK BUTTGEREIT

- Glucocorticoids act via a number of pathways including inhibition of transcription factors nuclear factor- κ B and activator protein 1.
- Glucocorticoids decrease synthesis of proinflammatory cytokines and proinflammatory enzymes, decrease T-cell function, and reduce Fc receptor expression.
- Short-term use of low-dose glucocorticoids in rheumatoid arthritis decreases clinical disease activity. These agents also have a beneficial effect on radiographic activity.
- Adverse events are common with these drugs, and many of the side effects are dose dependent. Careful titration of dose and strategies to minimize toxicity are essential when glucocorticoids are used.

INTRODUCTION

Discovered over 50 years ago, synthetic cortisone was first shown to be remarkably effective in relieving the inflammation associated with rheumatoid arthritis (RA).¹ This pioneering work by Hench, Kendall, and colleagues subsequently resulted in a Nobel Prize in Medicine. Despite the advent of many disease-specific therapies, the use of synthetic glucocorticoids in rheumatology remains a common, albeit controversial, therapy for many inflammatory disorders.

NOMENCLATURE AND PHARMACOLOGY

Preparations and structure

The term *corticosteroid* is often used synonymously with *glucocorticoid*, although glucocorticoid is the preferred designation when using exogenous agents therapeutically because corticosteroids encompass both glucocorticoid and mineralocorticoid hormones.² A variety of synthetic glucocorticoid preparations are commercially available and have variable chemical structure (Fig. 54.1), potency, and half-life (Table 54.1). The 11 β - and 17 α -hydroxyl groups are important for glucocorticoid activity, and prednisone, a synthetic analogue of cortisone, is also hydroxylated before becoming biologically active. The additional double bond in ring A of the resultant prednisolone enhances glucocorticoid activity without increasing mineralocorticoid activity, an effect that is increased by 6 α -methylation (to produce methylprednisolone) or 9 α -fluorination (triamcinolone) or both (dexamethasone). In rheumatology, the most commonly used oral glucocorticoids are prednisone and prednisolone, whereas methylprednisolone is the predominant preparation used parenterally.

Dosing

Thresholds for low, medium, and high dose are not well defined. Some rheumatologists consider 10 mg/day prednisone equivalent as the upper threshold of a low dose, whereas others use 7.5 mg/day³; this is actually somewhat above the daily endogenous production of cortisol (hydrocortisone) by the adrenal glands, which averages 5.7 mg/m²/day.⁴ A European League Against Rheumatism (EULAR) standing committee defined *low dose* as up to 7.5 mg/day, *medium dose* as more than 7.5 mg/day but less than or equal to 30 mg/day, *high dose* as more than 30 but mg/day less than or equal to 100 mg/day, and *very high dose* as more than 100 mg/day prednisolone

equivalent.² Dosing designations were considered based on the percent binding of the glucocorticoid receptors and the risk of perceived adverse effects. These dosing conventions are used throughout this chapter.

Bioequivalence and bioavailability

The different preparations of glucocorticoids have the same rate of gastrointestinal absorption. Most commercially available prednisone tablets are bioequivalent, independent of tablet strength,⁵ and the systemic bioavailability of prednisone and prednisolone are similar. Glucocorticoid bioavailability does not appear to be affected by pregnancy.

Metabolism and drug interactions

In contrast to endogenous cortisol, which is 80% bound, synthetic glucocorticoids bind poorly to cortisol-binding globulin (CBG, or transcortin). Prednisolone has about 60%, prednisone 5%, and methylprednisolone, dexamethasone, betamethasone, and triamcinolone less than 1% of the affinity of cortisol for CBG. Half-life ranges from about 1 hour for prednisone to over 4 hours for dexamethasone. Prednisone is rapidly metabolized in the liver by CYP3A4 (a cytochrome P450 isoform) to prednisolone; the elimination of prednisone is approximately 13 times faster than the elimination of prednisolone.⁶ Hyperthyroidism and nephrotic syndrome increase clearance, whereas aging and liver disease impair clearance. Prednisolone is preferred to prednisone in patients with significant hepatic dysfunction.

Enhancement of the rate of metabolism of some glucocorticoids has been noted with concurrent administration of phenobarbital, phenytoin, and rifampin (rifampicin). Concurrent use of aspirin and glucocorticoids decreases salicylate levels by causing an increased rate of salicylate metabolism.

Clearance and dose timing

The elimination half-life of prednisolone is approximately 3 hours.⁷ Total prednisolone clearance increases by 75% as the intravenous dose increased from 5 to 40 mg.⁸ Clearance also varies with the time of day. Both prednisolone and methylprednisolone clearance is up to 25% lower in the morning than in the evening.⁹ This property, in combination with the disruption of the usual cortisol diurnal rhythm by exogenous glucocorticoids, results in variations in efficacy when glucocorticoids are administered at different times during the day.¹⁰ Administration of short-acting glucocorticoids very early in the morning, in contrast to later in the day, better complements the normal diurnal variation in endogenous hormones and further blocks production of proinflammatory cytokines such as interleukin-6 (IL-6)¹¹ and inflammatory symptoms.¹² For example, a low-dose prednisone compound incorporating a modified-release mechanism (MR prednisone, i.e., drug is released 4 hours after ingestion) when taken in the evening reduced RA morning stiffness more than placebo at 12 weeks.^{13,14}

MR prednisone plus disease-modifying antirheumatic drug (DMARD) therapy resulted in significantly higher ACR20 response rates (percentage of patients achieving a 20% improvement in signs and symptoms according to American College of Rheumatology criteria) and a greater relative reduction in morning stiffness than placebo plus DMARD.¹⁵ Significantly greater reductions in severity of RA and fatigue, and a greater improvement in physical function also were seen at week 12 with MR prednisone compared with placebo.

Timing of administration of the glucocorticoid dose also influences toxicity. For example, daily split-dose therapy is more immunosuppressive and should be used for a shorter duration due to its more profound disruption of the normal hypothalamic-pituitary-adrenal (HPA) axis function.

STRUCTURE OF SOME NATURAL AND SYNTHETIC GLUCOCORTICOIDS

Fig. 54.1 Structure of some natural and synthetic glucocorticoids.

TABLE 54.1
Some commonly used glucocorticoids

Glucocorticoid	Equivalent oral dose (mg)	Plasma half-life (minutes)	Relative antiinflammatory effect	Relative mineralocorticoid effect
Cortisol	20	90	1	1
Prednisolone/prednisone	5	200	4	0.8
Methylprednisolone	4	200	5	0.5
Triamcinolone	4	200	5	0
Dexamethasone	0.75	300	25	0

One study found no differences between MR prednisone and standard prednisone with regard to influence on the HPA axis as measured by corticotropin-releasing hormone tests. In both treatment groups, there was a normal response in 50% of the patients, the response was suppressed in about 37%, and there was no response in about 13%.¹⁶

MECHANISMS OF GLUCOCORTICOID ACTION

Glucocorticoids act as antiinflammatory mediators via a number of pathways that continue to be further elucidated.¹⁷⁻²² Oral glucocorticoids at dosages of less than 30 mg/day prednisone equivalent circulate in the plasma and diffuse through the plasma membrane where they bind to the cytosolic glucocorticoid receptor, a 95-kDa phosphorylated protein. Diversity in the function of the glucocorticoid receptor is influenced by variations in genetic transcription mediated by alternative splice sites. The relative levels of the α and β receptors influence the sensitivity or resistance of cells to glucocorticoids. Glucocorticoid resistance is reported in patients with severe RA and has been associated with higher levels of glucocorticoid receptor β , activation of mitogen-activated protein kinases (MAPKs) that inhibit glucocorticoid signaling, or antibodies to lipocortin-1.²³⁻²⁶ Individuals with glucocorticoid receptor polymorphisms have higher sensitivity to exogenously administered glucocorticoids.²⁷ Persons with relative glucocorticoid resistance may have diminished *in-vitro* response of their peripheral blood

mononuclear cells to glucocorticoid stimulation.²⁸ Imbalances in the two isoforms of 11 β -hydroxysteroid dehydrogenase may play a central role in glucocorticoid resistance.²⁹

Glucocorticoids act on the cell through genomic and nongenomic paths in at least three ways (Fig. 54.2).²¹

- Heat shock protein chaperons the glucocorticoid/glucocorticoid receptor complex to the nucleus, where it binds reversibly and exerts potent effects on transcription via binding to positive and negative glucocorticoid response elements in promoter or suppressor sites of target genes. The detailed mechanism of a direct transrepression via the binding of glucocorticoid receptors to simple DNA binding sequences has been elucidated.³⁰
- The glucocorticoid/glucocorticoid receptor complex inhibits transcription factors such as nuclear factor- κ B (NF- κ B) and activator protein 1. Most antiinflammatory effects are thought to occur due to inhibited gene transcription via these effects on NF- κ B (transrepression), whereas the adverse effects of glucocorticoids, such as metabolic side effects, are mediated in large part via activation of transcription of certain genes (transactivation) (Fig. 54.3). However, this concept has recently been challenged.^{30a}
- Glucocorticoid signaling occurs through membrane-associated receptors and second messengers (nongenomic pathways). The glucocorticoid receptor gene encodes for both cytosolic and membrane-bound

Fig. 54.2 As lipophilic substances, glucocorticoids pass very easily through the cell membrane into the cell, where they bind to ubiquitously expressed cytosolic glucocorticoid receptors (cGCRs). This is followed either by the classic cGCR-mediated genomic effects (I) or by cGCR-mediated nongenomic effects (II). Moreover, the glucocorticoid is very likely to interact with cell membranes, either via specific membrane-bound glucocorticoid receptors (mGCRs) (III) or via nonspecific interactions with cell membranes (IV). HSP, heat-shock protein; m., mechanism. (Adapted from Buttgerit F, Straub RH, Wehling M, Burmester GR. Glucocorticoids in the treatment of rheumatic diseases: an update on the mechanisms of action. *Arthritis Rheum* 2004;50:3408-17.)

glucocorticoid receptor.³¹ At high glucocorticoid dosages (more than 100 mg/day prednisolone equivalent), glucocorticoid receptors become saturated and these nongenomic effects emerge. They are also mediated by incorporation of glucocorticoid molecules into cell membranes.¹⁹

The relative contributions of these three mechanisms are not yet fully understood, but in combination they result in the decreased synthesis of proinflammatory cytokines such as IL-1, IL-2, IL-2 receptor, interferon- α , IL-6, and tumor necrosis factor- α (TNF- α).^{17,18,32} Glucocorticoids increase the rate of synthesis of lipocortin (annexin I), which inhibits phospholipase A₂. Phospholipase A₂ converts membrane-bound phospholipids into arachidonic acid with the subsequent intracellular production of prostaglandins, leukotrienes, and oxygen radicals.³³ Glucocorticoids also induce MAPK phosphatase 1 (which inactivates all proteins of the MAPK family including Jun N-terminal kinase), and glucocorticoids repress transcription of cyclooxygenase 2.³⁴ Independent of change in gene expression, glucocorticoids exert rapid effects via activation of endothelial nitric oxide as well as

activation of β -adrenoreceptors, endonucleases, and neutral endopeptidases, which explains other observed effects.³⁵ Glucocorticoids, even in very low concentrations, inhibit the synthesis of a variety of proinflammatory enzymes including the macrophage products collagenase, elastase, and plasminogen activator.³⁶ Glucocorticoids have a direct effect on lymphocytes by decreasing T-cell function and circulating number. They further inhibit Fc receptor expression (reducing clearance of antibody-coated blood cells), increase the number of circulating neutrophils, and affect leukocyte adhesion to endothelial cells.³⁷

Drug development efforts are attempting to exploit an improved knowledge of the molecular biology of glucocorticoids. Selective glucocorticoid receptor agonists that differentially affect levels of transactivation and transrepression have been under development.^{38,39} In preliminary experiments some compounds appeared to exhibit antiinflammatory effects similar to those of traditional glucocorticoids but may have fewer adverse effects such as blood glucose elevation or skin thinning.^{40,41} Liposomal glucocorticoids are being developed with the aim of providing more prolonged

Fig. 54.3 Binding of the glucocorticoid/cytosolic glucocorticoid receptor (cGCR) complex to glucocorticoid response elements (GREs) leads to expression of antiinflammatory and regulatory proteins such as interleukin-10 (IL-10) or IκB (transactivation). A suppressed synthesis of proinflammatory proteins (transrepression) is caused by competition for nuclear coactivators or by direct or indirect interaction with transcription factors. AP-1, activator protein 1; COX-2, cyclooxygenase 2; IκB, inhibitor of NF-κB; IFN-γ, interferon-γ; NF-AT, nuclear factor of activated T cells; NF-κB, nuclear factor-κB; STAT5, signal transducer and activator of transcription 5; TF, transcription factor; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor. (Adapted from Stahn C, Buttgerit F. Genomic and nongenomic effects of glucocorticoids. *Nat Clin Pract Rheumatol* 2008;4:525-33.)

concentrations of glucocorticoids at the site of inflammation and lower plasma levels. Part of their mechanism of action may be via insertion of higher concentrations of glucocorticoids into cell membranes.⁴²

EFFICACY

Efficacy in rheumatoid arthritis

Short- to moderate-term glucocorticoid studies reveal improvement in disease activity and functional status compared with control therapy.^{43,44} In many past studies, the antiinflammatory benefits of glucocorticoids declined after the first year⁴⁵⁻⁴⁷ and often were not seen even beyond 5 months.^{48,49} In contrast to earlier reports, three more recent randomized controlled trials

showed that at 2 years treatment with either 5 mg or 7.5 mg of prednisone^{50,51} or 10 mg of prednisone⁵² resulted in variable levels of improvement in joint indices, functional status, and remission criteria compared with placebo.

In addition to disease activity, joint damage as assessed by radiographic criteria (bony erosions and joint space narrowing) is a critical efficacy outcome. Although it is known that methotrexate, the anti-TNF agents, and newer biologic response modifiers are DMARDs in RA, there is now consensus that glucocorticoids function similarly. Many of the RA studies evaluating the effects of glucocorticoids on radiographic progression are summarized in Table 54.2. Findings that DMARDs, biologic agents, and glucocorticoids had similar effects on radiographic progression in RA were confirmed in a meta-analysis.⁵³ Many of the studies investigating the efficacy of glucocorticoids allowed concomitant use of DMARDs, which makes it

TABLE 54.2
Studies of oral glucocorticoid therapy and radiographic progression in rheumatoid arthritis (RA)

Study	Experimental group	Control group	Study type (no. of subjects)	Effect on radiologic progression	Comments
MRC (1955) ¹⁴⁹	Cortisone (69 mg/day)	ASA	CT (100)	No difference	Trend toward protective effect
MRC (1959) ¹⁵⁰	Prednisolone (initially 20 mg, 12 mg/day by yr 1, 10 mg/day by yr 2)	ASA	CT (77)	Reduction after 2 yr, less after 3 yr	Control patients offered prednisolone in yr 3
Berntsen & Freyberg (1961) ¹⁵¹	Various glucocorticoids, dose not reported	IM gold, analgesics	Retrospective (388)	Deterioration in all groups	Other treatments had already failed in many patients
Harris et al (1983) ¹⁵²	Prednisone (5 mg/day) & DMARD	PBO & DMARD	DB RCT (34)	No significant difference	Trend toward reduction
Million et al (1984) ¹⁵³	Prednisolone (10.3 mg/day) & DMARD	No prednisolone	RCT (103)	Significant reduction	10-yr study
Kirwan (1995) ⁴⁵	Prednisolone (7.5 mg/day) & DMARD	PBO & DMARD	DB RCT (106)	Significant reduction	
Boers et al (1997) ⁴⁸	Prednisolone (60 mg/day with taper) & MTX, SSZ	PBO & SSZ	DB RCT (102)	Significant reduction	
Hansen et al (1999) ⁴⁹	Prednisolone (6 mg/day) & DMARD	DMARD	RCT (102)	No significant difference	Trend toward reduction
van Everdingen et al (2002) ⁹⁶	Prednisolone (10 mg/day) & SSZ as rescue	PBO & SSZ as rescue	DB RCT (81)	Significant reduction	Only study since the MRC studies not allow to background DMARDs; SSZ allowed after 6 mo
Cappell et al (2004) ⁹⁵	Prednisolone (7 mg/day) & SSZ	PBO & SSZ	DB RCT (167)	No significant difference	Discordance between readers in radiographic interpretations
Wassenberg et al (2005) ⁵¹	Prednisolone (5 mg/day) & either AU or MTX	PBO & either AU or MTX	DB RCT (166)	Significant reduction	Relatively new-onset RA; one of lowest dosages to show radiographic protection
Svensson et al (2005) ⁵⁰	Prednisolone (7.5 mg/day) & DMARD	No prednisone & DMARD	Open RT (225)	Significant reduction	Early RA
Bakker et al (2012) ⁵²	Prednisone (10 mg/day) & MTX	PBO & MTX	DB RCT (236)	Significant reduction	Early RA; tight RA control sought with monthly methotrexate dose adjustments

ASA, high-dose aspirin; AU, auranofin; CT, controlled trial; DB, double-blind; DMARD, disease-modifying antirheumatic drug; IM intramuscular; MRC, Medical Research Council; MTX, methotrexate; PBO, placebo; RCT, randomized controlled trial; RT, randomized trial; SSZ, sulfasalazine.

difficult to discern the independent effects of glucocorticoids. Although many of the earlier investigations failed to demonstrate a benefit of low-dose glucocorticoids on radiographic progression, an increasing number of placebo-controlled randomized or open-label clinical trials have now demonstrated that low-dose glucocorticoids prevent radiographic joint destruction in RA. Although the overwhelming majority of glucocorticoid use internationally in RA is via lower-dose oral therapy,^{3,54} a few RA studies have examined other approaches such as pulse-dose and intramuscular depot administration.^{55,56} The addition of prednisone to a methotrexate-based therapy aimed at “tight control” resulted in a significantly greater reduction in radiographic damage.⁵²

Efficacy in systemic connective tissue disorders and vasculitis

Medium- to high-dose glucocorticoids are the therapeutic mainstay in rheumatology for managing serious inflammatory disorders with life- or organ-threatening manifestations. Glucocorticoids have been used to treat serious extraarticular manifestations of RA including interstitial lung disease, bronchiolitis obliterans with organizing pneumonia, pericarditis, scleritis, and vasculitis.⁵⁷

For these serious sequelae of RA, and in other major inflammatory disorders such as systemic lupus erythematosus (SLE), inflammatory myopathy, and systemic vasculitis, glucocorticoids are typically started at dosage in the range of 1 mg/kg/day of prednisone equivalent. Although highly effective in producing remission or improving control of these disorders, glucocorticoids do not inhibit the generation of platelet-derived thromboxane, and in certain forms of vasculitis patients can develop progressive ischemia despite glucocorticoid therapy.⁵⁸

For life- or organ-threatening complications, intravenous pulse therapy is used at dosages of 250 to 1000 mg/day of methylprednisolone for a typical treatment period of 3 days. The intent of pulse therapy is to rapidly and aggressively suppress severe systemic inflammation while minimizing exposure to prolonged very-high-dose therapy. Rapidly progressive glomerulonephritis as well as pulmonary and central nervous system vasculitis are among the disorders for which very-high-dose pulse therapy has been

advocated.^{59,60} Compared with prednisolone, methylprednisolone has more than threefold more nongenomic effects at equivalent dosages, which contributes to the preference for methylprednisolone over prednisone in this setting.⁶¹

Efficacy in polymyalgia rheumatica and large-vessel vasculitis

Glucocorticoids are the mainstay of therapy for polymyalgia rheumatica (PMR), giant cell (temporal) arteritis, and Takayasu arteritis.^{62,63} Due to the older age of most people with PMR and giant cell arteritis, glucocorticoids need to be used cautiously and monitored more closely in this population. Although a variety of other immunosuppressive agents have been tested as possible glucocorticoid-sparing agents, there are few compelling data that these agents are effective alternatives to glucocorticoids for treatment of these disorders. A typical prednisone starting dosage in giant cell arteritis is 60 mg/day, whereas 15 to 20 mg/day is usually adequate for PMR. Although efforts to taper glucocorticoids are initiated early in the disease course, over 6 months may be necessary to reach a low dose in persons with giant cell arteritis.⁶⁴ It is not uncommon for patients with giant cell arteritis to require in excess of 2 years of glucocorticoid therapy. Glucocorticoid-tapering regimens for PMR are not well standardized, and symptoms often wax and wane over many years, remaining partially responsive to low-dose prednisone. Guidance from a meta-analysis suggests that once a prednisone dosage of 10 mg/day is reached, tapering by 1 mg/mo or less results in fewer relapses.⁶⁵

ADVERSE EFFECTS

Despite the considerable benefits of glucocorticoids in controlling serious inflammation and improving functional status in a plethora of disorders, serious adverse effects dampen enthusiasm, particularly for its long-term use. Most studies of glucocorticoid toxicity tend to be retrospective and observational. The difficulty in differentiating adverse outcomes attributable to glucocorticoids from those occurring due to the underlying diseases or

other comorbidities confounds potential associations. A strong physician selection bias for glucocorticoid use exists because physicians are inclined to treat patients with more severe disease with glucocorticoids (i.e., confounding by indication). The use of glucocorticoids at variable points in the disease course, limited data defining the threshold dose for particular adverse events,⁶⁶ and toxicity reports for a heterogeneous group of glucocorticoid-treated diseases all further hinder interpretation of these data.

Several large retrospective reviews indicate that long-term, relatively low-dose glucocorticoid use is a significant independent predictor of numerous potentially serious adverse events.^{58,67-69} Lending further credibility to causality is the fact that the association between glucocorticoid use and adverse events was both dose and time dependent (Fig. 54.4). Both cumulative and mean glucocorticoid dose are independently associated with adverse

events. There appear to be two distinct dose-related patterns of adverse events⁷⁰: (1) a linear increase with increasing dose was found for a cushingoid phenotype, ecchymosis, leg edema, parchment-like skin, and sleep disturbance; (2) a threshold pattern showing an elevated frequency of events beyond a certain threshold value was observed for glaucoma, depression and listlessness, and increases in blood pressure. Dosages of 5 mg/day or more were associated with epistaxis and weight gain (Fig. 54.5).

Less serious adverse effects (e.g., skin thinning, cushingoid appearance) are often of great concern to patients, whereas more debilitating toxicities, such as vertebral fractures and cataracts, initially may be unrecognized or asymptomatic.⁷¹ Compared with other antirheumatic agents, glucocorticoids have a low incidence of short-term symptomatic toxicity, and patients uncommonly discontinue therapy for this reason. What follows is an overview of the most common adverse effects that have been associated with glucocorticoid use. Recent international recommendations provide guidance on the safe use of glucocorticoids.⁷²

Bone and muscle effects

Glucocorticoid-induced osteoporosis is the most potentially devastating complication of protracted glucocorticoid therapy. It is estimated from observational studies that as many as 40% of glucocorticoid users develop bone loss leading to fracture.⁷³ Although glucocorticoids diminish sex hormone production and decrease circulating levels of receptor activator of NF- κ B ligand (RANKL), both of which lead to enhanced osteoclast-mediated bone resorption, a direct glucocorticoid-induced defect in bone formation is thought to be the predominate pathway of importance.^{74,75} Glucocorticoid-induced osteoporosis initially affects trabecular bone. However, with long-term glucocorticoid use, cortical bone at sites such as the femoral neck is also affected.⁷³ Comparison of the results of studies examining the bone effects of glucocorticoids is made difficult by the differences in timing of glucocorticoid initiation, variable dosing regimens, and use of different bone mass measurement techniques and disparities in the sites of measurement.

Observational studies of RA and other glucocorticoid-requiring diseases show a mean first-year loss of bone ranging from 1.5% to 20% at a dosage of 10 mg/day or less of prednisone.³⁸

With continued use, bone loss remains greater than normal and is estimated to be approximately 1.5% to 3% per year, depending on dose, in subsequent years. Although a decline in bone mineral density (BMD) is strongly correlated with fracture risk, the rate of bone turnover, bone quality, and other factors also play important roles.⁷⁶ Some data suggest that at very low doses, glucocorticoids prevent bone loss in RA because of their inhibitory effects on proinflammatory cytokines that modulate osteoclast activity as well as their beneficial effects on functional status, which promotes more weight-bearing activities.^{77,78} Several studies including a meta-analysis have failed to demonstrate an association of low-dose glucocorticoid use with low axial BMD, even in the setting of an increased fracture rate.⁷⁸⁻⁸¹ However,

Fig. 54.4 Probability of remaining free from adverse events (AEs) over time in patients receiving low-dose (less than 5 mg), intermediate-dose (5 to 10 mg), or high-dose (more than 10 to 15 mg) prednisone compared with a control group. (Adapted from Saag KG, Koehnke R, Caldwell JR, et al. Low dose long-term corticosteroid therapy in rheumatoid arthritis: an analysis of serious adverse events. *Am J Med* 1994;96:115-23.)

Fig. 54.5 Two distinct patterns of glucocorticoid-induced adverse events related to dose and duration of glucocorticoid intake have been observed: a linear pattern (a) and a threshold pattern (b). Graphs show percentage of unselected patients with rheumatoid arthritis in routine practice who experienced various health problems while taking glucocorticoids based on self-report (n = 1066). BP, blood pressure. (Adapted from Huscher D, Thiele K, Gromnica-Ihle E, et al. Dose-related patterns of glucocorticoid-induced side effects. *Ann Rheum Dis* 2009;68:1119-24.)

the presence of biochemical changes in bone remodeling with very-low-dose oral⁸² or even intraarticular⁸³ administration argues against a “safe” glucocorticoid dose from the standpoint of bone.⁸⁴

The confounding effects in trying to identify an association between glucocorticoid treatment and osteoporosis in RA relate to two principal issues: the heightened risk of osteoporosis caused by the RA disease process itself⁸⁵⁻⁸⁷ and a higher rate of osteoporosis in postmenopausal women, the demographic group with the highest prevalence of RA.⁸⁸

Given the inconsistent findings of BMD studies and the knowledge that fractures in glucocorticoid-treated patients occur at a higher BMD and depend on other factors,^{89,90} it is necessary to examine long-term studies that evaluate actual fracture incidence. In a large cohort of RA patients,⁹¹ 34% of more than 300 women taking a mean dose of prednisone of 8.6 mg/day had a self-reported fracture within 5 years. Two case-control studies of hip fracture in patients both with and without RA showed a twofold increased risk even after adjustment for the presence of RA.^{85,92} Cohort studies identify fractures as one of the most commonly documented complications of supraphysiologic glucocorticoid use.^{67,68,93} Hip and other nonvertebral fractures occur with glucocorticoids in both a dose- and time-dependent fashion.^{84,94} Nevertheless, randomized controlled trials involving the most common glucocorticoid-requiring illness, RA, have not confirmed an increased rate of fracture.^{45,50,51,95,96} However, none of these trials has been large enough or long enough to fully clarify the magnitude of the fracture risk, some have not systematically assessed fracture outcomes in all patients, and in at least one,⁹⁵ patients were allowed to use bone-protective medications.

Considerable advancement has occurred in the development of antiosteoporotic therapies, and numerous clinical trials have specifically tested such therapies in patients newly initiating glucocorticoid treatment and receiving long-term glucocorticoid therapy. All RA patients with or at risk of glucocorticoid-induced osteoporosis should receive initial therapy with adequate calcium and vitamin D,^{97,98} and strong evidence-based consideration should be given to the addition of a bisphosphonate⁹⁹⁻¹⁰³ or even potentially raloxifene as an alternative.¹⁰⁴ Teriparatide, which may directly inhibit glucocorticoid-mediated deleterious effects on bone formation, is another treatment option for glucocorticoid users at high risk of fracture.¹⁰⁵ Internationally, a variety of specialty societies have promulgated recommendations for appropriate testing and treatment to prevent glucocorticoid-induced osteoporosis.¹⁰⁶⁻¹¹¹

Osteonecrosis is a significant problem in patients receiving high-dose glucocorticoids, particularly for treatment of SLE. Osteonecrosis is more strongly associated with the peak dose of glucocorticoid than with the cumulative dose,¹¹² perhaps owing to osteocyte and osteoblast apoptosis.⁷⁵ The presence of antiphospholipid antibodies contributes to osteonecrosis independent of glucocorticoid use. Osteonecrosis is seldom seen when the prednisone dosage is maintained at less than 20 mg/day.¹¹³

Like osteonecrosis, myopathy occurs very rarely in patients receiving glucocorticoids at low doses. In patients with inflammatory myopathy it is often difficult to disentangle ongoing muscle inflammation from glucocorticoid myopathy. Gradual muscle improvement with dose reduction is often a diagnostic clue because electromyography and muscle biopsy findings are often insufficiently specific to differentiate these two entities. Based on small studies, fluorinated glucocorticoid preparations, such as triamcinolone, are more strongly associated with myopathy than prednisone.¹¹⁴ Myopathy has been reported to occur at a dosage as low as 8 mg/day of triamcinolone after only 3 months of treatment. In general, myopathy attributable to prednisone requires a higher dose and longer duration of treatment.

Cardiovascular effects

Glucocorticoids at medium to high dose promote fluid retention based in some¹¹⁵ but not all^{116,117} studies. This can be problematic for patients with underlying heart or kidney disease, although susceptibility is modified by both glucocorticoid dose and dietary factors. Patients with essential hypertension require closer surveillance of blood pressure and may need modification of their antihypertensive regimens while receiving glucocorticoid therapy. In some studies glucocorticoids, at even low or moderate doses, have been associated with hypertension, but this may be a reflection of channeling bias due to RA disease severity.¹¹⁸ Glucocorticoids can cause sodium retention and can potentiate vasopressor response to catecholamines and angiotensin II. In patients receiving less than 10 mg/day, age and elevated pretreatment blood pressure likely better explain significant hypertension than the use of glucocorticoids.¹¹⁹ There is inconsistent information on the effects of glucocorticoids on serum lipid profiles.¹²⁰⁻¹²³ To date, randomized controlled trials have not identified low-dose glucocorticoid therapy as an additional risk factor for dyslipidemia.

Another difficult-to-study potential toxicity of low-dose glucocorticoids is the development of premature atherosclerotic vascular disease. Increasing attention to the importance of accelerated atherosclerotic disease in RA and other inflammatory conditions has raised interesting questions about the role of chronic inflammation on the vascular endothelium.¹²⁴ Although atherosclerotic vascular disease is known to be accelerated in patients with Cushing disease and at least one study showed increased carotid plaque and decreased arterial compressibility in RA patients receiving glucocorticoids,¹²⁵ there are insufficient data to confirm an independent risk in patients taking low-dose glucocorticoids, in particular. A systematic review of low-dose glucocorticoid therapy,¹²⁶ somewhat in contrast with the lipid results, reported that four out of six studies reviewed found low-dose glucocorticoid therapy to be associated with major cardiovascular events, including myocardial infarction, stroke, mortality and a composite index of cardiovascular events. Nonetheless, one of the largest and most carefully conducted cohort studies did not find an increased cardiovascular risk with dosages of less than 7.5 mg/day of prednisone.¹²⁷ There is also evidence that glucocorticoids may tend to have a protective vascular effect in persons with polymyalgia rheumatica.¹²⁸

Cardiac arrhythmias have been described during pulse-dose glucocorticoid therapy. This rare occurrence, reported mostly in patients with renal disease, calls for a preinfusion check of serum electrolyte levels and strong consideration of cardiac monitoring during infusion. The use of slower infusion rates (administration over 1 to 2 hours) may reduce this concern.

Dermatologic effects and appearance

Even at a low dose, skin thinning and ecchymoses are one of the most common glucocorticoid adverse events. A cushingoid appearance manifests as moon facies, truncal obesity, and buffalo hump and is very troubling to patients, but it is uncommon at doses below the physiologic glucocorticoid replacement range. Moon facies develops in slightly over 10% of patients receiving even short-term low-dose therapy. Use of an alternate-day schedule decreases the incidence of cushingoid appearance. Steroid acne and, to a lesser extent, hirsutism and stria are other undesirable dermatologic adverse effects that can occur even at lower doses. Glucocorticoids also impair wound healing by inhibiting the synthesis of matrix metalloproteinases and collagen.¹²⁹ Weight gain and fat redistribution occur at moderate to high doses, in particular. The effects of hyperinsulinemia on leptin, increased adipocyte conversion of cortisone to cortisol, and increased appetite all contribute to weight gain and fat redistribution.

Gastrointestinal effects

Although glucocorticoids are considerably less toxic to the upper gastrointestinal (GI) tract than nonsteroidal antiinflammatory drugs (NSAIDs), glucocorticoids slightly increase the risk of adverse GI events such as gastritis, ulcers, and GI bleeding. The increased risk of GI events with glucocorticoid use is very small, with estimated relative risks varying from 1.1 (not significant) to 1.5 (marginally significant).^{130,131} In addition to reports of upper GI morbidity, there are case reports of intestinal rupture, diverticular perforation, and pancreatitis thought to be caused by glucocorticoids. Glucocorticoids frequently are used concurrently with NSAIDs in rheumatology, and the combination synergistically results in a higher risk of GI adverse events. Glucocorticoids cause a nearly twofold increased risk of GI adverse events among NSAID users,¹³² and the combined use of NSAIDs and glucocorticoids results in a more than fourfold increased risk of GI adverse events compared with nonusers.¹³¹

Infectious diseases

Moderate- to very-high-dose glucocorticoid therapy leads to an increased risk of serious infections. However, no studies have adequately explored the risk of infection in patients treated with low-dose glucocorticoids. The risk of infection appears to be lessened by initiating alternate-day therapy. The association of glucocorticoids with infectious adverse events becomes an even greater concern if glucocorticoids are used in combination with biologic antirheumatic agents.¹³³ Among patients in the Consortium of Rheumatology Researchers of North America registry who were prescribed methotrexate, TNF antagonists, or other DMARDs, low-dose prednisone use overall was not associated with increased risk of infection.¹³⁴ In a nested case-control study, the adjusted relative risk increased from 1.10 for dosages of less than 5 mg/day to 1.85 for dosages of more than 20 mg/day. Although the overall relative risk was low at 1.20, the absolute risk was high, with one additional infection seen for every 13 patients treated with glucocorticoids (at all dosage levels) for 1 year.¹³⁵ In a study of RA patients comparing

infection risk with biologic therapies to that with nonbiologic DMARDs, glucocorticoid use was the factor most associated with serious infection outcomes.¹³⁶ A meta-analysis of 71 controlled clinical trials involving over 2000 patients randomly allocated to receive systemic glucocorticoids in the setting of different diseases, the relative risk for infectious complications overall was 1.6 (95% confidence interval, 1.3 to 1.9). The rate was not increased in patients given a daily dose of less than 10 mg or a cumulative dose of less than 700 mg of prednisone.¹³⁷ Similarly, a different systematic review identified 15 studies assessing infection risk of low-dose glucocorticoid therapy in RA patients and did not find consistent associations between infection risk and low-dose glucocorticoid treatment.^{35,134-137} At higher doses, glucocorticoids appear to be a risk factor for tuberculosis.¹³⁸

Metabolic and endocrine effects

Glucocorticoid users with diabetes mellitus commonly have higher blood glucose levels while taking glucocorticoids. Moreover, in patients with early diabetes or glucose intolerance new-onset hyperglycemia or, rarely, a non-ketotic hyperosmolar state can develop *de novo*. Ketosis is very rare in glucocorticoid-associated diabetes, because the gluconeogenic and glycogenic effects of glucocorticoids offer protection against this complication. It is uncommon for frank diabetes to develop as a result of glucocorticoid therapy. A recent, small, randomized trial of short-term treatment with prednisolone 60 mg or 30 mg per day demonstrated no deterioration of glucose tolerance in patients with active RA.^{138a}

A significant concern with long-term glucocorticoid use is HPA insufficiency. HPA insufficiency is both dose and duration specific. High-dose therapy results in protracted suppression of adrenocorticotrophic hormone release and adrenal hyporesponsiveness in as little as 5 days. More typically, adrenal suppression can be detected in 6 weeks at 10 mg/day and in 4 weeks at 15 mg/day.⁶⁶ Spontaneous recovery of the HPA axis is normal in patients taking 5 mg or less of prednisone; however, even subphysiologic dosages (less than 7.5 mg/day) given for long periods may lead to HPA blunting.¹³⁹ HPA suppression is worsened if glucocorticoids are given twice daily.

Neuropsychiatric effects

Patients taking even low-dose glucocorticoid therapy report a slight increase in their overall sense of well-being, which appears to be independent of improvement in disease activity. Symptoms of akathisia (motor restlessness), insomnia, and depression are also occasionally observed in patients taking low-dose therapy. Memory impairment can occur even at low doses, particularly in older patients. Daily split-dose therapy, in particular, tends to be troublesome because the evening dose promotes sleep disturbances. True glucocorticoid psychosis is distinctly uncommon at dosages of less than 20 mg/day of prednisone.

Ophthalmologic effects

The development of posterior subcapsular cataracts is a well-described complication of prolonged glucocorticoid use. There is no minimal safe dose with respect to this complication, and reports exist of cataract formation even with the use of inhaled glucocorticoid preparations.¹⁴⁰ Although a very-low-dose glucocorticoid threshold was seen for cataracts (less than 5 mg/day) in one study,⁵⁴ cataracts rarely occur in patients taking less than 10 mg/day for less than 1 year.^{141,142} Nearly a third of RA patients taking a mean dosage of 8 mg/day for an average of 7 years developed cataracts.⁶⁷ Cortical cataracts also have also been associated with glucocorticoid use.¹⁴³

In addition to cataracts, glucocorticoid-treated patients can develop increased intraocular pressure, which can lead to visual disturbances. The development of frank glaucoma is rare, particularly with low-dose therapy, and it tends to appear in patients who are otherwise genetically predisposed.

GLUCOCORTICOID USE IN PREGNANCY

Glucocorticoids are often used in pregnant patients to control peripartum inflammatory disease activity. Although glucocorticoids are safer than many other antirheumatic agents during pregnancy, their use can cause fetal growth retardation and low birth weight of offspring. It is difficult, however, to fully discern whether these adverse fetal outcomes are caused by the glucocorticoids or by the underlying chronic inflammatory disorder. Prednisone or prednisolone is preferred over other glucocorticoids if the aim is

to treat a pregnant mother, because the placenta will convert active prednisolone back to prednisone and thereby limit fetal exposure. The American Academy of Pediatrics considers prednisone and its active metabolite prednisolone to be compatible with breastfeeding. Even at dosages above 1 mg/kg/day, the amount of glucocorticoid secreted into the breast milk is less than 10% of a nursing infant's endogenous cortisol production.

PRACTICAL RECOMMENDATIONS

Evidence-based treatment guidelines

In an era of internationally rising health care costs and highly efficacious but very expensive biologic disease-modifying agents, glucocorticoids provide an apparently inexpensive approach to management of inflammatory and autoimmune disorders. Although the cost per dose of oral glucocorticoid is low, other costs such as those associated with adverse effects must also be considered.¹⁴⁴ Monitoring for glucocorticoid adverse effects, as suggested by groups such as a EULAR task force,¹⁴⁵ may mitigate some but not all toxicities.

Once the decision is made to initiate glucocorticoid treatment, every effort should be made to use these agents as safely and effectively as possible. Accumulating data argue that more aggressive use of glucocorticoids earlier rather than later in the course of RA might be best. However, practitioners skeptical of the disease-modifying benefits of glucocorticoid therapy or excessively concerned about glucocorticoid adverse effects should strive to use the lowest effective dose. Despite the evidence and an international call to action to prevent glucocorticoid-induced osteoporosis among even long-term glucocorticoids users, fewer than half of all long-term glucocorticoid users are receiving adequate bone prophylaxis or evaluation.¹⁴⁶

Perioperative and stress-dose considerations

Long-term glucocorticoid users preparing for major surgery or undergoing considerable physiologic stress associated with severe illness should receive prophylactic stress-dose glucocorticoids, commonly in conjunction with a mineralocorticoid. Hydrocortisone at a dosage of 100 mg three times per day is empirically recommended, but for patients taking low-dose glucocorticoids or undergoing less significant physiologic insult, half this dose is often sufficient. Identifying which patients require stress-dose glucocorticoids requires consideration of both dose and duration of glucocorticoid use. Guidelines for low-dose use were discussed previously. Any person who has received more than 20 mg/day of prednisone equivalent for longer than 3 weeks or who has developed clinical Cushing syndrome should receive prophylaxis. If clinically feasible, the need for stress-dose glucocorticoids can be determined by testing for the responsiveness of the HPA axis using a low-dose synthetic adrenocorticotrophic hormone (cosyntropin) stimulation test.

Glucocorticoid use in children

Growth retardation can occur in children receiving glucocorticoids because these agents inhibit linear bone growth and delay epiphyseal closure. Regular daily administration of more than 7.5 mg prednisolone is associated with inhibition of linear growth. The mechanism of action is unknown, although suppression of growth hormone secretion and other metabolic effects can contribute. Alternate-day administration of the same total dose reduces this effect¹⁴⁷ and is preferred, if clinically practical.

Glucocorticoid withdrawal regimens and alternate-day therapy

There is little science to guide the necessary but challenging process of glucocorticoid dose reduction. In conditions such as RA, a very subtle dose reduction is most effective in promoting eventual glucocorticoid discontinuation. In SLE and other diseases in which immune complexes play a significant role in pathogenic consequences, alternate-day therapy is a consideration once disease control is achieved. Alternate-day therapy serves to minimize HPA axis suppression and, in turn, certain adverse effects, and it affords a reduction in cumulative glucocorticoid dose. In RA, however, alternate-day therapy often is not well tolerated due to an increase in joint symptoms on days off therapy.

Steroid withdrawal syndrome is not clearly associated with HPA insufficiency but presents as extreme weakness and arthralgias. Glucocorticoid tapering from 20 mg/day by increments of 2.5 mg/day every 2 weeks resulted in rebound deterioration in over half of RA patients.⁴⁶ Although

convenience and individual patient disease response should be accommodated, a relatively stable decrement of 10% to 20% of glucocorticoid dose every 1 to 2 weeks is recommended until the dose reaches 10 mg; then tapering should proceed more slowly for long-term users. Indeed, the difficulty in withdrawing patients from glucocorticoids is sometimes cited as a compelling reason for not initiating them.¹⁴⁸ Many rheumatologists report significant difficulties in tapering glucocorticoids in most RA patients, and

abrupt withdrawal can result in dramatic flares in disease activity. Thus it is recommended that in patients receiving long-term low-dose glucocorticoids for inflammatory arthritis or polymyalgia rheumatica the dose be lowered in increments as small as 1 mg/mo (sometimes facilitated by cutting the dose on alternate days) to maximize their prospects for successful withdrawal. However, further research on appropriate tapering regimens is greatly needed.

Nonimmunosuppressive disease-modifying antirheumatic drugs

■ VIVIAN P. BYKERK

- Several nonimmunosuppressive disease-modifying antirheumatic drugs (DMARDs), including antimalarials, parenteral gold, sulfasalazine, tetracyclines, and bucillamine, are still actively being used and continue to be investigated for the treatment of rheumatic diseases.
- Rheumatic diseases amenable to treatment with these nonimmunosuppressive DMARDs include rheumatoid arthritis, systemic lupus erythematosus, spondyloarthritis, and in some cases, osteoarthritis.
- DMARDs have a superior safety profile from the standpoint of risk for infection or malignancy.
- DMARDs also have relatively low cost.
- Because the precise role of DMARDs in the sequence of treatment strategies is still not entirely agreed on, further studies are needed. For example, the comparative effectiveness of combinations of DMARDs versus newer biologic therapies or immunosuppressive oral therapies should be studied in the context of cost-effectiveness, ability to halt damage and improve function and quality of life, and relative safety.
- Of all these DMARDs, the role of hydroxychloroquine is most intriguing given its potentially additive metabolic benefits.

INTRODUCTION

During the last 10 years, paradigm shifts in treating rheumatoid arthritis (RA) have included a treat-to-target approach in which the goal of therapy for RA has been to achieve remission and, when not possible, achieve a state with low disease activity instead.¹ Although most practice recommendations and guidelines propose that methotrexate (MTX) should be the first-line therapy for inflammatory arthritis, nonimmunosuppressive disease-modifying antirheumatic drugs (DMARDs) have an ongoing role in the treatment of RA, inflammatory arthritis, and in the case of hydroxychloroquine (HCQ), systemic lupus erythematosus (SLE) as well. Furthermore, in some patients who cannot tolerate MTX or its use is contraindicated, other nonimmunosuppressive DMARDs can be viable and effective therapeutic options.

Some of these DMARDs have been studied more recently, such as HCQ and sulfasalazine (SSZ), whereas for others such as parenteral gold, tetracyclines, and bucillamine (BUC), fewer recent studies have been conducted and these drugs are being used less often for a variety of reasons. Although they are unrelated, all have the ability to suppress inflammation, improve symptoms and function, and possibly limit joint damage as evidenced by reduced progression of radiologic damage on radiographs of patients with RA.

Unlike the newer biologic drugs and corticosteroids, these DMARDs have a slower onset of action. Patients often need to wait at least 12 weeks for these agents to take effect and reduce the signs and symptoms of the inflammatory manifestations of arthritis and rheumatic diseases. These agents may also be reserved for the management of early and milder disease. In the case of moderate to severe RA, other therapies such as MTX are more often recommended because the DMARDs described in this chapter typically have a more delayed action, insufficient suppression of disease activity when used as monotherapy, and limited evidence of prevention of progression of joint damage. The exception is parenteral gold salts, which are the only agents that have been shown to slow radiographic damage and induce

remission in early RA. Interest in antimalarials, primarily HCQ, has been renewed because they have benefits in a number of rheumatic diseases and may have additional metabolic and antithrombotic benefits. Antimalarials and SSZ are no longer the initial treatment of choice as monotherapy for RA. Nonetheless, when taken in combination with MTX, these agents are still often used for the treatment of inflammatory arthritis and related conditions. Gold salts, tetracyclines, and BUC are being used less often for rheumatic diseases but merit discussion as treatment options. Based on published evidence over the past 15 to 20 years, tetracyclines, particularly minocycline, are used as an alternative to MTX for early arthritis, primarily as a result of a series of studies indicating a positive effect on RA. Studies of doxycycline have generated interest in their use as possible adjunctive therapy for osteoarthritis (OA), although it is doubtful that these agents are having an antimicrobial effect. In this chapter nonimmunosuppressive DMARDs are reviewed.

PARENTERAL GOLD

Introduction

Since 1935, following a report from Jacques Forestier,² injectable gold compounds came into use and have been successful in treating RA. Gold sodium aurothiomalate has been the most extensively studied by scientists and clinicians. In the 1980s, the oral gold compound auranofin was used temporarily as an alternative to injectable gold but fell out of favor because of its lower efficacy and higher rate of side effects. Of the injectable gold compounds, gold sodium thiomalate, which is 50% gold by weight, continues to be the preferred gold compound for the treatment of RA. The application of gold compounds is called “chrysotherapy.”

Use of gold is now uncommon despite evidence of the clinical efficacy of injectable gold sodium aurothiomalate. However, several authors contend that given the benefits shown in several placebo-controlled trials, injectable gold compounds can still play a valuable role and indeed may be the correct first choice for the management of RA.³

STRUCTURE OF SODIUM AUROTHIOMALATE

Pharmacology

After intramuscular (IM) injection, gold is rapidly absorbed into the circulation, where most of it is bound to albumin.⁴ Its peak serum concentration is reached within 2 to 4 hours after injection.⁵ Gold is slowly eliminated from the body, mostly via the kidney and the remainder in feces. It can be found in tissues up to 20 years after the last dose.⁶

Mode of action

The exact mechanisms responsible for the therapeutic effects of gold on RA are not fully understood. Several lines of evidence suggest that the free thiol group plays a key role in reducing oxidative stress.⁷ Studies evaluating the effect of gold in the synovium suggest that it reduces monocytes and macrophages, as well as the proinflammatory cytokines interleukin-1 α (IL-1 α), IL-1 β , IL-6, and tumor necrosis factor- α (TNF- α).^{8,9}

Efficacy

IM gold reduces the number of inflamed joints and decreases laboratory measures of inflammation when compared with placebo. In a study comparing IM gold with MTX 15 mg/wk, IM gold appeared to be as effective as MTX.^{10,11} Observational studies and short-term trials indicate that gold slows radiologic progression.¹² In a 2-year, randomized, placebo-controlled multicenter trial of combination MTX and IM gold therapy, 65 RA patients who had a suboptimal response to 12 weeks or more of MTX therapy were randomly assigned to add weekly IM gold or placebo to MTX. Adding IM gold weekly resulted in significant clinical improvement. Named for the American College of Rheumatology, the ACR20, ACR50, and ACR70 response rates in the IM gold patients compared favorably with those in the placebo group. IM gold–related adverse events led to discontinuation in 11% of the gold group over the course of the study.¹³

Toxicity

In general, IM gold leads to higher dropout rates because of its side effects in comparison to other DMARDs, including MTX.¹⁴ In one study 19% of patients had reactions to gold sodium aurothiomalate.¹⁵

The most common complications are dermatitis (rash, pruritus) and stomatitis; however, serious renal and hematologic reactions can occur (Table 55.1). Cutaneous reactions and occasionally proteinuria and a reduction in white cell counts can often be managed by temporarily stopping use of the drug and continuing at a lower dosage.^{16,17} Proteinuria occurred in clinical trials in less than 5% of patients. Mild proteinuria may resolve spontaneously even after decreasing the dose, but nephrotic syndrome has been described and aurothiomalate should be stopped if severe proteinuria develops.¹⁸

Approximately 5% of patients treated with aurothiomalate experience nitritoid reactions consisting of transient symptoms of flushing, sweating, dizziness, nausea, hypotension, and malaise that occur within minutes of drug administration.¹⁹ Patients who use angiotensin-converting enzyme inhibitors appear to be especially at risk and should receive gold therapy while in the recumbent position. Aplastic anemia is the most serious and rarest complication of gold treatment. Between 1965 and 1971 the British Committee on Safety of Medicines reported nine fatal episodes of aplastic anemia in patients treated with injectable gold. Thrombocytopenia, the most common hematologic effect that occurs with injectable gold therapy, occurs

in less than 5%. It will usually develop within the first 6 months of treatment and is generally related to immune-mediated destruction with an active bone marrow.²⁰ Other rare complications that have been described are enterocolitis, hepatotoxicity, pancreatitis, peripheral neuropathy, cranial nerve palsies, and a Guillain-Barré–like syndrome. Chrysiasis, a slate-gray skin pigmentation of sun-exposed skin that develops after long-term parenteral gold therapy, was recently reported to occur in a patient after laser therapy.²¹ Limited published information is available on the safety of gold in pregnancy,²² but it may be a treatment option in women planning pregnancy.²²

Dosage and monitoring

An initial dose of 10 mg, followed by a 25-mg dose the next week, is typically given to test for possible hypersensitivity. Thereafter, 50 mg/wk is given until disease activity is sufficiently reduced or until 20 weekly doses of 50 mg have been administered. Clinical effect may be delayed for 12 to 20 weeks. Once a good clinical response is achieved, the dose should be reduced to a maintenance level (often 50 mg monthly) by increasing the interval between injections up to once per 6 weeks. Regular blood tests to detect thrombocytopenia, anemia, and leukopenia and urinalysis to check for proteinuria are recommended before each injection.

BUCILLAMINE

Introduction

BUC is a DMARD known to be an analogue of D-penicillamine that was introduced in the 1980s for the treatment of RA. D-Penicillamine was historically used as a DMARD in many Western countries during the 1970s and 1980s. Because of only moderate efficacy and a disproportionately high incidence of side effects, it was effectively abandoned in place of more effective DMARDs such as MTX. BUC reportedly has fewer side effects than D-penicillamine does and has been used widely as one of the first-line DMARDs for RA in Japan and Korea. It is approved in Asia only for the treatment of RA.

STRUCTURE OF BUCILLAMINE

■ TABLE 55.1

Adverse reactions reported with the use of parenteral gold

Skin and mucous membranes	Pruritus and rash (30%) ranging from simple erythema to exfoliative dermatitis and mucous membrane lesions (20%), including stomatitis
Hematologic	Leukopenia (2%), thrombocytopenia (<5%), eosinophilia, agranulocytosis, and rarely aplastic anemia
Renal	Proteinuria (10%-15%), nephrotic syndrome, acute renal failure
Allergic	Anaphylactoid and vasomotor (nitritoid) reactions (5%)
Gastrointestinal	Metallic taste, diarrhea, enterocolitis, cholestatic jaundice, transaminitis, pancreatitis (<5%)
Chrysiasis	Affects skin and mucous membranes. Corneal gold deposits have been noted in some patients
Neurologic (rare)	Peripheral neuropathy, cranial nerve palsies, a Guillain-Barré–like syndrome, encephalitis
Miscellaneous rare reactions	Pulmonary infiltrates

Modified from <http://products.sonofi.co/en/myochrysine.pdf>.

Pharmacology

BUC, a thiol compound [N-(2-mercapto-2-methylpropionyl)-L-cysteine], differs from D-penicillamine by the presence of two free sulfhydryl groups and has two S-H bonds in its chemical structure.²³

Mode of action

BUC is considered to be a DMARD with immunologic effects. It has been shown to suppress IL-6 and IL-8 production by synovial cells in vitro and is thought to have pharmacologic actions that are different from those of D-penicillamine.²⁴ In an in vitro study of its effect on T-cell proliferation, cytokine production, and migration of T cells, BUC significantly inhibited T-cell proliferation, reduced the expression of CD44 on T cells, and inhibited the production of IL-2, interferon- γ (IFN- γ), TNF- α , and IL-6, thus indicating that it is an inhibitor of type 1 T helper–type cytokine production, proinflammatory cytokine production, and transendothelial migration of T cells.²⁵ The latter appears to be mediated partly through the reduced expression of CD44, an adhesion molecule on the T-cell surface.

Efficacy

The beneficial effects of BUC for the treatment of RA have been published in several observational studies and clinical trials, with varying effects reported. In a retrospective cohort study of 86 patients with active RA who

received BUC between 1998 and 2004, 20% reported improvement from 44% to 56% in ACR core set measures 6 months after initiation of therapy, 50% reported improvement of between 22% and 34% in ACR core set measures, and 70% reported improvement between 11% and 19% in ACR core set measures 6 months after initiation of therapy.²⁶ A 16-week open-label trial of BUC (300 mg/day) suggested that this agent is effective as a slow-acting drug for RA in patients who had previously failed gold salt or D-penicillamine therapy.²⁷ In a small randomized controlled trial (N = 46) of D-penicillamine and BUC, BUC was found to be at least as effective as D-penicillamine in improving the swollen joint count, tenderness score, morning stiffness, modified health assessment questionnaire, and erythrocyte sedimentation rate (ESR). It was more effective in terms of improvement in the tender joint count, grip strength, C-reactive protein, and rheumatoid factor titer. However, responses were low, with only 27% of the BUC group and 33% of the D-penicillamine group responding to treatment.²⁸

In a cross-sectional analysis from the IORRA study, a long-term observational database, responses to BUC treatment were noted to be better in males, in patients with a shorter duration of illness, and in those who were rheumatoid factor negative. In a longitudinal analysis from the same study, European League Against Rheumatism improvement criteria were higher in patients receiving BUC (41.0%) than in those receiving MTX (33%) or SSZ (26%).²⁹

A multicenter trial of BUC known as the SNOW study was conducted in patients with early RA. In this 24-month study of 81 DMARD-naïve patients with early RA, 87.5% showed moderate improvement in their 28-joint disease activity score (DAS28). After 24 months of BUC therapy, 7 patients (43.8%) met the remission criterion of a DAS28 lower than 2.6, and 60.5% of patients continued BUC either as monotherapy or in combination with other DMARDs after 24 months.³⁰ A multicenter, double-blind controlled trial studying a combination of MTX and BUC was performed in 71 patients with active early RA within 2 years of onset. Patients received 8 mg MTX with 5 mg folic acid per week, 200 mg BUC per day, or both. After 96 weeks they noted an ACR20 response rate of 79.2% in the combination group but only 44% in the MTX group ($P = .01$) and 46% in the BUC group ($P = .02$). Also, the combination group exhibited significantly less radiographic progression (total Sharp score over a 96-week period of 12.6 ± 9.0 versus 28.0 ± 28.3 for the single-therapy arms; $P = .05$). No increased rate of adverse events was noted in the combination group in comparison to the single-therapy group.³¹ However, in a recent review examining changes in the use of nonbiologic DMARDs in Japan, use of BUC alone appeared to be decreasing and use of MTX appeared to be increasing. BUC was also being more often used in combination with MTX.³²

Adverse effects

Proteinuria is reported to be the most frequent adverse effect of BUC. In one report, 10 cases of nephrotic syndrome were noted. Most cases occurred within the first 4 months of use. Discontinuation led to resolution of this complication within 1 year. In patients with BUC-induced proteinuria and membranous nephropathy, immediate withdrawal of BUC resulted in complete resolution of the proteinuria without any deterioration in renal function. Thus, monitoring of urinary protein is important when using this agent.³³ BUC-induced yellow nail syndrome (a triad of yellow nails, lymphedema, and pulmonary manifestations) was recently described in a review of 36 cases reported mostly in Japanese medical journals.³⁴ Most of these patients (90%) showed improvement in their yellow nails after discontinuation of BUC, but the lymphedema and pulmonary manifestations improved only in 31% and 35% of patients, respectively. Other rare side effects include skin disorders manifested as a rash, which can be vesicular or involve swelling of the lips. Less frequently reported adverse effects include hepatitis³⁵ and bone marrow suppression.³⁶ At least 15 cases of BUC-induced pulmonary injury have been reported. Advanced age was associated with the development of severe interstitial pneumonia, and pulmonary complications were reported to be resistant to corticosteroids and life-threatening, especially in the elderly.^{37,38} One case of bronchiolitis obliterans-organizing pneumonia has been reported during treatment with BUC.³⁹

Dosage and monitoring

Typical doses of BUC range from 100 to 300 mg daily. Monitoring should include regular assessment of blood counts and urinalysis for proteinuria. Patients should be evaluated for efficacy by 3 months to determine their response to this therapy.

SULFASALAZINE

Introduction

In 1938 Svartz⁴⁰ first synthesized what is now called SSZ. SSZ was introduced as a drug for RA only in the late 1970s. McConkey⁴¹ and others reported beneficial effects of SSZ for RA with fewer side effects than with the then-standard drugs gold and penicillamine. Because of initial underwhelming responses to SSZ in patients with severe RA, it fell out of favor and became a treatment of inflammatory bowel diseases. Studies in the Netherlands in patients with new-onset RA demonstrated it to be effective, however, and it continues to be studied and used in combined regimens to this day.^{42,43}

Pharmacology

SSZ is a prodrug that is metabolized in the large intestine by bacterial enzymes into sulfapyridine, which is absorbed, and 5-aminosalicylic acid (5-ASA), which is excreted mostly via the bowel. Any intact SSZ that is absorbed is highly protein bound and excreted unchanged in urine with an elimination half-life of 5 hours.⁴⁴ Sulfapyridine and SSZ have been found in synovial fluid at slightly lower concentrations than in plasma.⁴⁵

Mode of action

The mode of action of SSZ is unclear. Intact SSZ, sulfapyridine, and 5-ASA are all biologically active, but sulfapyridine seems to be the most relevant component in the treatment of RA. Recent studies show scavenging effects of SSZ and its metabolites on reactive oxygen and nitrogen species, so SSZ may mediate its antiinflammatory effects through prevention of oxidative/nitrate/nitrosative damage.⁴⁶ Earlier studies suggested that SSZ may reduce inflammation in RA through the effects of sulfapyridine by reducing secretion of the inflammatory chemokines IL-8, GRO- α , and monocyte chemoattractant protein-1.⁴⁷

Efficacy

Placebo-controlled trials have shown a benefit of 2 g/day of SSZ in reducing the inflammatory activity and radiographic progression of RA.^{12,48} SSZ is likely to be as effective as lower doses of MTX, although it is usually no longer recommended as monotherapy for RA. It is still considered a treatment option as monotherapy for spondyloarthritis.^{49,50} In observational studies of RA, SSZ tends to be used in seronegative patients with lower disease activity, and even so, the effectiveness of SSZ is slightly less than that of MTX.⁵¹ Several randomized controlled trials of SSZ versus other DMARDs, either alone or in combination, have demonstrated effectiveness of this agent.⁵²⁻⁵⁵ A meta-analysis of four randomized trials studying the effect of combined MTX and SSZ versus SSZ monotherapy in naïve and experienced patients showed that the combination was more effective in patients who had an inadequate response to SSZ monotherapy. However, in patients who had never received either drug, responses to SSZ were similar to those to lower-dose MTX, and the combination of SSZ and MTX was more effective in SSZ/MTX-naïve patients.⁵⁶ Four randomized controlled trials were identified to compare the efficacy of combination MTX and SSZ with that of either drug alone. Two parallel trials were performed in patients naïve to both drugs, and two add-on trials were performed in SSZ failures. In the trials with naïve patients, the mean improvement in DAS with combination MTX and SSZ pointed to an additive effect by SSZ. In the trials with patients who previously failed to respond to SSZ, the mean changes in DAS for combination MTX and SSZ therapy also indicated additive efficacy. These authors concluded that in patients with RA, addition of MTX to SSZ is a beneficial therapeutic option for SSZ failures whereas the combination

of MTX and SSZ in DMARD-naïve patients has no added value. In a more recent trial of patients with very early RA, induction therapy with a combination of DMARDs, including HCQ and SSZ together with temporary use of glucocorticoids, was found to be better than MTX monotherapy in inducing remission in RA.⁴³

SSZ may be most effective in the treatment of RA when used in combination with other DMARDs as part of a dynamic treatment strategy aiming for tight control with the goal of reaching a target of low disease activity or remission. Overall, taking evidence of the efficacy of SSZ into account in the treatment of RA, current recommendations favor initial MTX over SSZ. If SSZ is to be used, it should be considered as part of combination DMARD therapy because of favorable long-term clinical and radiologic efficacy and low toxicity profile.⁵⁷⁻⁵⁹

In clinical studies of axial spondyloarthritis, modest benefits of SSZ have been demonstrated. In a recent study comparing the effectiveness of SSZ and etanercept, more patients receiving etanercept reached clinical and magnetic resonance imaging remission at week 48 than did SSZ-treated patients. However, no difference was found in the flare rate in patients receiving these two treatment options, thus suggesting that SSZ may have some efficacy in this disease.⁶⁰

Toxicity

The most common adverse effects of SSZ are minor gastrointestinal, central nervous system, and cutaneous side effects. The withdrawal rate because of side effects is approximately 25%.⁶¹ Symptoms include anorexia, headache, vomiting, diarrhea, gastric distress, and nausea. Pruritic rash occurs in about 5% of patients. Rash is more likely to occur in those with a history of sulfa allergy. Leukopenia occurs in less than 3% of patients and is usually mild and transient, but serious agranulocytosis, a rare event, has been observed, generally in the first 6 weeks of treatment.⁶² Less frequently reported problems include a decrease in immunoglobulins, megaloblastic anemia, hepatotoxicity (usually mild), eosinophilic pneumonia, and anaphylactic reactions.^{63,64} Temporary oligospermia may occur in men taking SSZ. SSZ is generally thought to be safe during pregnancy but should be given with a folic acid supplement. In some cases of milder disease it could be used as an alternative to MTX in women who want to become pregnant during treatment. SSZ should be used cautiously in women who are breastfeeding because sulfapyridine concentrations in breast milk are 40% to 50% of those found in maternal serum.⁶⁵

Dosage and monitoring

The standard dose of SSZ is 2 g/day, but it may be increased to 3 g/day. Nausea is usually transient during the first few days of treatment or when the dosage is increased and can be prevented by using a protocol of gradually increasing the dosage (e.g., start with 0.5 g/day and increase to 2 g/day over a period of 3 weeks). Patients who start SSZ should be instructed to consult a physician if they have a fever with or without a sore throat because this could be a manifestation of underlying agranulocytosis. Routine laboratory tests are recommended once monthly in the initial 3 months and once every 3 months during long-term treatment.

HYDROXYCHLOROQUINE

Introduction

Antimalarials have been used for rheumatic diseases since the early 1950s after several case series reported various antimalarials to be efficacious in

the treatment of RA. When compared with other immunosuppressive and biologic therapies, the relative effectiveness of HCQ is smaller; however, HCQ is often used as adjunctive therapy in combination regimens for RA and is the most common antimalarial used for SLE. Another antimalarial—chloroquine—though still available, is rarely used given the superior safety profile of HCQ.

Pharmacology

After oral absorption ($\approx 70\%$),⁶⁶ HCQ is cleared rapidly from plasma and distributed in tissues, including muscle, liver, spleen, kidney, lung, and hematopoietic cells. Steady-state concentrations are not achieved for at least 3 months.⁶⁷ Higher loading dosages are associated with more rapid beneficial clinical effects, but also with more frequent adverse gastrointestinal side effects, and are therefore not usually recommended. Excretion of HCQ is mostly by renal clearance. Its elimination half-life is approximately 40 days. Small amounts of chloroquine (a related antimalarial) were found in plasma, red blood cells, and urine several years after the last dose of chloroquine. HCQ may lead to increased plasma digoxin levels⁶⁸ and can increase the bioavailability of β -blockers.⁶⁹ Concomitant use of MTX does not appear to affect the pharmacokinetics of HCQ.⁷⁰

Mode of action

Antimalarials may have varying modes of action. Initially, antimalarials were thought to act by affecting phagosomal and lysosomal function.⁷¹ However, recent studies suggest that antimalarials exert an impact through inhibition of intracellular Toll-like receptors (TLRs), particularly TLR9.⁷² This effect on TLRs may mediate the effects of HCQ in patients with SLE, RA, and possibly also diabetes and hyperlipidemia.⁷¹ HCQ-related clinical improvement has also been correlated with reductions in IFN- α levels, thus underscoring the importance of these cytokines in the pathogenesis of SLE.⁷³ In addition, recent data have shown that antimalarials may have a potential role in treating antiphospholipid syndrome by affecting annexin-5 binding.⁷⁴ A recent study by Rand and colleagues⁷⁵ showed that HCQ abrogates the binding of aPL- β_2 GPI complexes to the phospholipid bilayer of target cells. Recent data in patients with SLE also suggest that those who reach a target blood concentration closer to 1000 ng/mL have fewer flares of SLE.⁷⁶

Efficacy

Rheumatoid arthritis

A meta-analysis evaluating the efficacy of antimalarials for RA indicated that they have moderate efficacy when used alone for the treatment of RA.⁷⁷ In an analysis of randomized trials of HCQ versus placebo in 300 patients assigned to HCQ therapy and 292 to placebo, a statistically significant benefit was observed when HCQ was compared with placebo. The standardized mean differences for the clinical outcome measures ranged from -0.33 to -0.52 , and these differences were statistically significant. Statistically significant differences were also observed for ESR. Overall withdrawals because of lack of efficacy were significantly more frequent in the placebo group. No differences were observed in withdrawals as a result of toxicity. Of note, no study has shown that HCQ monotherapy induces remission of RA or that it prevents radiographic damage. Currently, HCQ is typically part of a combined DMARD regimen for the treatment of RA known as “triple therapy,” which includes SSZ, MTX, and HCQ. This regimen has been included in several studies evaluating treat-to-target strategies. They were outlined in the section on SSZ in this chapter.

Systemic lupus erythematosus

Studies proving HCQ to be effective in the management of SLE were first reported in the early 1990s, and as a result, HCQ is commonly used for the treatment of joint and cutaneous manifestations of the disease, as well as to prevent disease flares.⁷⁸ HCQ is commonly used for SLE and has been shown to markedly improve disease prognosis.⁷⁹ A systematic review concluded that HCQ is an effective and safe medication to administer to patients with SLE and that its use should be encouraged at all stages of disease.⁸⁰ Despite data in animal studies proposing that there may be a rationale for HCQ playing a role in treating antiphospholipid syndrome, there is limited experimental and clinical evidence of its antithrombotic effects, and at this point it could be considered as adjunctive therapy because it is not associated with major bleeding side effects. Further controlled studies are needed to establish the efficacy and safety of HCQ for the management of refractory antiphospholipid syndrome.⁸¹

STRUCTURE OF HYDROXYCHLOROQUINE

Metabolic effects

In patients with comorbid cardiovascular disease, diabetes, and dyslipidemia associated with these diseases, there may be a rationale to use HCQ for its purported metabolic benefits.⁸² HCQ also has known benefits in reducing some traditional cardiovascular risk factors, such as hyperlipidemia and diabetes mellitus, and may have a role as an antithrombotic drug in patients with SLE and those with antiphospholipid antibodies.⁷⁹ In a retrospective cohort of 1127 adults with newly diagnosed RA studied in an administrative database, patients receiving HCQ had a lower incidence rate of diabetes than did those who did not receive it.⁸³ This benefit has also been confirmed in a larger study showing a reduced risk for diabetes in patients initiating HCQ versus other nonbiologic DMARDs.⁸⁴ Other studies suggest that HCQ may reduce the risk for future development of diabetes in RA patients.⁸³ It has also been associated with lower fasting glucose levels in both RA and SLE patients⁸⁵ and a more favorable lipid profile, including reduced low-density lipoprotein and triglycerides and increased high-density lipoprotein.⁸⁶

Toxicity

Antimalarials are considered to be among the safest of drugs used for RA. The most common side effects involve the gastrointestinal tract (nausea, anorexia, muscle-related abdominal cramps in <10%), the skin (especially a pruritic rash in <5%), and the eyes (<0.1%).⁸⁷ Retinopathy, which can lead to impaired vision, appears to be extremely rare, especially in the first 5 years of therapy.⁸⁸ Figure 55.1 shows examples of how the retina can be affected by antimalarials.⁸⁹ Screening guidelines tailored to different ages and risk groups have been published.⁹⁰ An uncommon but important side effect of antimalarials is neuromyotoxicity with proximal lower extremity weakness, normal creatine phosphokinase, and abnormal muscle and nerve biopsy results.^{91,92} Therapy with HCQ is thought to be safe during pregnancy and lactation.⁹³⁻⁹⁵

Fig. 55.1 Examples of retinal changes induced in susceptible patients treated with antimalarial agents. (From Shroyer NF, Lewis RA, Lupski JR. Analysis of the ABCR [ABCA4] gene in 4-aminoquinoline retinopathy: is retinal toxicity by chloroquine and hydroxychloroquine related to Stargardt disease? *Am J Ophthalmol* 2001;131:761-6).

Dosing of hydroxychloroquine

Revised recommendations have been published indicating that the dose of HCQ should be reduced to 6.5 mg/kg/day in people whose lean body weight is less than 60 kg (135 lb). Thus, most males less than 163 cm (5 feet 4 inches) tall or women less than 167 cm (5 feet 6 inches) tall would need their dose reduced.⁹⁰ Ototoxicity from antimalarials has been reported but is considered to be rare.⁹⁶ Symptoms of ototoxicity can occur quickly—within 24 hours after initiation of an antimalarial drug—but these complications are more often reported after at least 1 month of antimalarial drug use.

TETRACYCLINES

Introduction

Tetracyclines were first considered as possible antibiotic therapy for RA in the 1960s when RA was hypothesized to be caused by infection with *Mycoplasma* or similar organisms. Two decades later, Brown and Scammell used antibiotics (not only tetracyclines) for the treatment of RA and published their results in a lay textbook.⁹⁷ This caused significant interest in patients living with arthritis, and thus research involving antibiotics was reinitiated in the 1980s to test new semisynthetic tetracyclines for the treatment of RA when they were discovered to have antiinflammatory, immunomodulatory, and chondroprotective properties.⁹⁸ Minocycline and doxycycline were shown to have modest clinical benefit in RA. Yet despite positive reports of the benefits of tetracyclines, the use of MTX and biologic agents is greater given their additional benefit of halting radiographic progression and larger beneficial effects on clinical outcomes. Furthermore, the use of tetracyclines has been hampered by reports of hyperpigmentation and drug-induced lupus. In one report of 27 patients who experienced hyperpigmentation with minocycline, this was the main reason for stopping use of this drug (41%).⁹⁹ Hyperpigmentation has been reported in many tissues, including bone, as was reported in a 55-year-old woman undergoing total knee arthroplasty.^{100,101} Given what has seemed to be modest effects of these tetracyclines clinically and because of the unproven effect of their halting radiographic damage, it remains to be determined whether tetracyclines will have a significant role in patients with RA or other rheumatic conditions. Some propose that there may be potential for their use as a disease-modifying drug for OA because of their ability to inhibit matrix metalloproteinase (MMP). Others argue that therapies for OA directed at cartilage protection are essentially futile.¹⁰² This section of the chapter reviews issues involving the use of tetracyclines, particularly minocycline and doxycycline, for rheumatic diseases.

CHEMICAL STRUCTURE OF MINOCYCLINE

Pharmacology and drug interactions

Tetracyclines are readily absorbed from the gastrointestinal tract; they circulate bound to plasma proteins. Tetracyclines are concentrated in the liver in bile and excreted in both urine and feces in their active form (serum half-life of 11 to 22 hours in individuals with OA and normal renal function). In subjects with impaired renal or hepatic function, the half-life has been shown to vary from 11 to 69 hours. Absorption is not affected by most types of food but is impaired by aluminum-containing compounds and by calcium, magnesium, and iron preparations. Food containing calcium (dairy products) may also affect absorption. Tetracyclines form a stable calcium complex in bone-forming tissue and can cross the placenta, thus potentially negatively affecting development of the fetal skeleton. They may also produce permanent yellow, gray, or brown tooth discoloration and should not be administered to children or pregnant women.¹⁰³

Because tetracyclines can depress plasma prothrombin activity, patients taking warfarin may need their dose decreased. For reasons that are unclear, oral contraceptives have been shown to be less effective in patients treated with tetracyclines; additional contraceptive measures should be recommended in patients taking both together.¹⁰⁴

Tetracyclines for the treatment of rheumatoid arthritis

Efficacy data

Randomized controlled trials of minocycline

To date, four large double-blind, randomized clinical trials have used minocycline for RA.¹⁰⁵⁻¹⁰⁸ Three of these trials were conducted in the United States and one in Europe (Table 55.2). Overall, the results are consistent among the four studies and favor the use of minocycline for the treatment of RA to improve clinical and laboratory parameters. In a second study by O'Dell and colleagues from the RAIN Network, an even better response to minocycline than to HCQ was demonstrated. In two of these studies O'Dell and colleagues were able to gather longitudinal data on their patients.¹⁰⁹ Genetic studies were performed in the Minocycline in Rheumatoid Arthritis (MIRA) study; white subjects with the shared epitope were more likely to respond to minocycline treatment than were those without it.¹¹⁰

Randomized controlled trials of doxycycline

Two small double-blind, randomized clinical trials of short duration in which doxycycline was used for RA have also been published.^{111,112} In these studies doxycycline failed to reduce either disease activity or joint

destruction. Thus it is unlikely that further studies of doxycycline for the treatment of RA will be undertaken.

In one trial conducted for 2 years that included 66 early rheumatoid factor–positive DMARD-naïve patients with RA, subjects were randomized to (1) oral MTX alone, (2) 20 mg oral doxycycline twice daily with oral MTX, or (3) 100 mg oral doxycycline twice daily with oral MTX. The results showed that initial therapy with MTX plus doxycycline was superior (based on an ACR50 response) to treatment with MTX alone. These authors concluded that because the therapeutic responses to low-dose and high-dose doxycycline were similar, the antimetalloproteinase effects of tetracyclines may be a more important mechanism than the antibacterial effects in patients with RA.¹¹³

Meta-analysis of minocycline and doxycycline for rheumatoid arthritis

A meta-analysis of the treatment of RA with tetracyclines has since been conducted and has integrated the results from randomized controlled trials studying tetracyclines (one tetracycline study, six minocycline studies, and three doxycycline studies).¹¹⁴ It included a review of data reported on 535 patients. The investigators confirmed that a small reduction in tender and swollen joint counts was found in tetracycline-treated patients as opposed to those treated with placebo. In addition, a marked reduction in the ESR was noted in the tetracycline-treated group, although these effects were more evident in the subgroup of patients with early rheumatoid factor–positive disease (disease duration <1 year). Minocycline was found to be more effective than doxycycline. No difference was found in radiologic progression (erosions and joint space narrowing) between both treatment groups, which could be due to true lack of efficacy or the result of patient selection (milder disease activity). Moreover, radiographic outcome was not the primary endpoint, and these studies could have been underpowered to detect an effect. In summary, the data modestly favor the use of minocycline over the control treatment groups for RA.

Long-term data

Long-term efficacy data have been systematically assessed only in the studies of O'Dell and colleagues.^{106,109} Four years later, more patients randomized to minocycline in the first study were still receiving this compound or were in remission (or both) than were those randomized to placebo. Efficacy was still observed in the second study 2 years later.

Toxicity data

In terms of toxicity, the MIRA study reported some adverse reactions, but they were comparable in frequency and severity in the placebo- and minocycline-treated patients. In contrast, in the study from the Netherlands,

TABLE 55.2
Outcome data for randomized clinical trials of minocycline for rheumatoid arthritis

	Kloppenburg trial (N = 50) ¹⁰⁵	MIRA study (N = 219) ¹⁰⁷	RAIN network minocycline study 1 (N = 46) ¹⁰⁸	RAIN network minocycline study 2 (N = 80) ¹⁰⁶
Trial location	Netherlands	USA	USA	USA
Trial design	6-mo multicenter RCT; 200 mg minocycline vs. placebo	48-wk multicenter RCT	6-mo multicenter RCT, 100 mg minocycline bid vs. placebo	2-yr multicenter RCT, 100 mg minocycline bid vs. 200 mg hydroxychloroquine bid
Patient group	Established RA >10-yr duration, failed ≥1 DMARD	Established RA, failed ≥1 DMARD	DMARD naïve, IgM rheumatoid factor positive; <1 yr of disease duration	DMARD naïve, IgM rheumatoid factor positive; <1 yr of disease duration
Background DMARDs allowed	Yes	No	No	No
Results	Statistically significant reductions in Ritchie articular index, ESR, and IgM rheumatoid factor (all at least $P \leq .01$); radiographic outcomes showed no difference between study groups	More with reduced joint swelling (54% vs. 39%) and reduced joint tenderness (56% vs. 41%) in the minocycline-treated group ($P < .023$); more ESR normalization in the minocycline-treated group ($P < .001$)	65% of the minocycline group met 50% improvement for 6 mo vs. 13% treated with placebo ($P < .001$)	>60% ACR50 response at 2 yr in minocycline-treated patients vs. 33% in hydroxychloroquine-treated patients ($P = .04$); less prednisone in minocycline-treated patients ($P < .01$). More minocycline patients completely tapered off prednisone ($P = .03$)
Adverse events	GI, dizziness, headaches, pneumonitis			

ACR, American College of Rheumatology; bid, twice daily; DMARD, disease-modifying antirheumatic drug; ESR, erythrocyte sedimentation rate; GI, gastrointestinal; RA, rheumatoid arthritis; RCT, randomized controlled trial.

some patients in the minocycline group experienced vestibular manifestations that led to falls and even some fractures. Rare manifestations associated with the use of minocycline include lupus-like syndromes. The original study from O'Dell's group demonstrated an impressive tolerability to minocycline, and only three patients (13%) withdrew from the 23 participants enrolled in the minocycline group, either because of cutaneous changes (fingernail discoloration and an erythematous rash) or dizziness. Of interest, in their second study, a 4 year follow-up, pigmentary changes were observed in four of the patients, out of the 30 in the minocycline group (13.3%); one patient chose to continue treatment with minocycline. In the meta-analysis 381 patients were included but there were no statistical differences in the risk for adverse events between both treatment groups.

Use of minocycline is well documented to cause cutaneous hyperpigmentation, although it is not frequently observed in initial clinical trials of RA. Four types of minocycline-induced hyperpigmentation are recognized, including (1) blue-black macular pigmentation confined to previous scars or inflammatory tissue on the face; (2) blue-black, brown, or slate-gray macules seen on healthy skin, mainly of the shins, forearms, or legs; (3) symmetric muddy-brown pigmentation of sun-exposed skin; and (4) blue-gray discoloration within scar tissue on the back.¹⁰¹ Figure 55.2 shows an example of these pigmentary changes in a patient with RA treated with minocycline for more than 5 years.

Dose-related toxicities associated with the use of tetracycline derivatives include vestibular dysfunction (dizziness, tinnitus, vertigo), gastrointestinal upset, pancreatitis, and hepatitis, whereas SLE, headaches, benign intracranial hypertension, and Stevens-Johnson syndrome are more rare and idiosyncratic.¹¹⁵

Fig. 55.2 Pigmentary changes in a patient with rheumatoid arthritis treated with minocycline for more than 5 years. (a) Pigmentation observed around a bunionectomy scar and on the shins after 5 years of treatment. Pigmentation over the bunionectomy scar worsened. (b) Pigmentation around the superior crux and conch of the pinna and oral mucosa after 5 years of treatment. (Courtesy Dr. Graciela S. Alarcón.)

Tetracyclines for the treatment of osteoarthritis

Efficacy data

In vivo studies have shown that oral doxycycline administration decreases the progression of OA in animal models. Thus, a multicenter, double-blind controlled study was conducted to compare oral doxycycline (100 mg twice a day) and placebo for 30 months in 431 obese women with unilateral knee OA confirmed by conventional standing views of knee radiographs (Kellgren grade II to III in the OA knee and 0 to I in the other).^{116,117} The primary outcome was changes in the joint space width of the medial tibiofemoral compartment.¹¹⁶ Patients in the doxycycline group experienced 33% less joint space narrowing in the OA knee (0.30 ± 0.60 mm versus 0.45 ± 0.70 mm, adjusted $P > .017$) but not in the contralateral knee as compared with the placebo group. No differences were noted in terms of pain score (Western Ontario and McMaster Universities [WOMAC] Osteoarthritis Index and 50-ft walk pain), WOMAC function, and median scores of patient and physician global assessment of disease activity between the doxycycline and placebo groups. Nonetheless, the frequency at which subjects reported a 20% or greater increase in knee pain (WOMAC pain score) in follow-up visits was reduced in the doxycycline group in comparison to the placebo group (23.8 ± 22.7 versus 30.2 ± 21.1 , $P > .004$). However, a recent triple-blind randomized trial of 100 mg doxycycline twice daily for OA showed that doxycycline was not effective in reducing symptoms in patients with knee OA over a 24-week study period and was associated with an increased risk for adverse events.¹¹⁸ Similarly, another study was unable to show clinical improvement in knee OA but did show slowing of joint space narrowing in a doxycycline-treated group versus a placebo-treated group.¹¹⁷ In terms of adverse events, photosensitivity, nonspecific gastrointestinal manifestations, and candidal vaginitis were reported more frequently in the doxycycline group than in the placebo group, but only a few patients discontinued the study prematurely because of these untoward events. Of interest, patients in the doxycycline group reported fewer urinary tract infections and a trend toward fewer upper respiratory tract infections. Thus, the data to date indicating whether doxycycline is a promising agent for the treatment of OA are not hopeful.

Dosing and monitoring

Dosing of minocycline can range from 50 to 400 mg taken once or twice a day; however, the dose studied for rheumatic diseases was 100 mg twice daily. Minocycline must be taken 2 to 3 hours before or after taking any medications containing magnesium, aluminum, calcium, iron, zinc, or sucralate, all of which can bind with minocycline and prevent its full absorption. Doses need to be reduced in patients with chronic kidney disease. Dosages of doxycycline are usually 100 mg twice daily. Absorption of doxycycline is not markedly affected by food, and therefore it can be taken with meals. Complete blood cell counts and chemistry profile should be monitored every 3 months while treatment is continued.

Summary

Minocycline may be a reasonable alternative as adjunctive treatment in patients who are not responding to standard therapy and are unable to afford or tolerate other DMARDs or in whom anti-TNF- α agents are not options because of increased risk for infection, such as in patients with chronic lung infection. In some instances minocycline may be considered for patients with early new-onset RA whose disease course is not thought to be aggressive and in whom HCQ may also have been considered.

The benefit of using doxycycline in patients with knee OA has been demonstrated, with one study indicating slowing of radiographic progression and data indicating that there may be an effect of reducing pain. These data need to be further validated with longer follow-up before doxycycline can be widely used as an option for patients with mild to moderate knee OA.

Despite limited data supporting the beneficial antirheumatic effects of tetracyclines and their derivatives, possibly resulting from their inhibition of MMPs and other proinflammatory mediators, only a few small trials have shown any significant clinical benefit of these agents in the treatment of RA or OA, and at this time they cannot be widely recommended for use in rheumatic diseases. Additional research is needed to further explore whether they have a role to play. Nonetheless, patients continue to request these drugs, particularly those who experienced transient improvements in their RA when they received antibiotics for other reasons.

Methotrexate*

■ ALYSSA K. JOHNSEN ■ MICHAEL E. WEINBLATT

- Methotrexate, a structural analogue of folic acid, can be administered orally or parenterally to treat a variety of rheumatic diseases.
- Although the exact mechanism of the therapeutic action of methotrexate is unknown, suppression of inflammation, mediated by increases in adenosine, may play a central role.
- The effectiveness of methotrexate in treating rheumatoid arthritis was established by four separate randomized controlled trials and confirmed by meta-analysis.
- Careful monitoring of methotrexate therapy is required, although most adverse events are mild and do not require discontinuation of the drug.
- Even though methotrexate hepatotoxicity is most widely discussed, serious liver disease is rare and the risk can be reduced with careful monitoring.
- Because methotrexate is a known teratogen, effective contraception should be used by women with the potential for pregnancy.

INTRODUCTION

Methotrexate (MTX), first used to treat malignant disease more than 50 years ago, is now the most commonly prescribed disease-modifying antirheumatic drug (DMARD) for the treatment of rheumatoid arthritis (RA). Low-dose MTX is highly efficacious and with monitoring has an excellent safety profile.

PHARMACOLOGY

MTX is structurally similar to folic acid; it differs only by the substitution of an amine for a hydroxyl group in the pteridine ring and by the addition of a methyl group on the 10th nitrogen of para-aminobenzoic acid (Fig. 56.1).

The bioavailability of low-dose oral MTX is relatively high, but individual patient variability exists. At 7.5 mg/wk, oral and parenteral absorption is the same, but at doses of 15 mg/wk or higher, oral absorption may be decreased by as much as 30% in comparison to parenteral dosing. At doses of 25 mg or greater, the bioavailability of oral MTX ranges from 0.21 to 0.96 relative to subcutaneous administration.² A greater clinical response is seen with subcutaneous than with oral MTX at doses greater than 15 mg/wk.^{3,4} Oral absorption is limited because MTX is absorbed from the gastrointestinal tract primarily via a saturable active transport system. Splitting the dose of oral MTX (25 to 35 mg) into two divided doses taken on the same day improves bioavailability by 28% and is comparable to subcutaneous therapy.⁵ Although oral absorption is not affected by food intake, it can be reduced in the setting of intestinal pathology.

After absorption, 10% of MTX is converted in the liver to 7-hydroxymethotrexate, predicted by animal models to be less efficacious in treating arthritis.⁶ This conversion has been shown to vary among treated patients, and folic acid may interfere with this metabolic step by inhibiting the enzyme responsible.⁷ Approximately 50% of MTX is bound to albumin, whereas 90% to 95% of 7-hydroxymethotrexate is bound to albumin.⁸ The serum half-life of MTX ranges from 6 to 8 hours, and it should be undetectable in serum by 24 hours. MTX and its metabolite 7-hydroxymethotrexate

are excreted primarily in urine, although a small portion is also excreted in bile. Renal clearance is due to a combination of filtration and secretion in the proximal tubule with subsequent reabsorption in the distal tubule. Renal insufficiency can lead to toxicity caused by impaired clearance of MTX. Because the drug is not cleared by dialysis, dialysis is an absolute contraindication to the use of MTX. Excretion of MTX is inhibited by weak organic acids such as aspirin, nonsteroidal antiinflammatory drugs, penicillin G, and probenecid. This is generally clinically relevant only with higher-dose MTX. Sulfonamides may also decrease renal tubular secretion and increase levels of MTX. Trimethoprim-sulfamethoxazole interferes with folic acid metabolism and may increase the risk for bone marrow suppression.⁹

Folates and antifolates enter the cell via two separate mechanisms. The reduced folate carrier (RFC) is a bidirectional anion exchanger that demonstrates higher affinity for MTX than for folic acid. In addition, MTX binds to folate receptors (FR- α and FR- β) and is transported inside the cell by endocytosis.¹⁰ Sulfasalazine is a noncompetitive inhibitor of the RFC and decreases the effects of MTX in cultured cells.¹¹ This inhibition of the RFC may decrease additive efficacy when combining sulfasalazine with MTX.

Inside cells, up to six glutamate residues can be added to MTX, but MTX PG₁ (native form) to MTX PG₅ have been reported to account for 99.6% of the total intracellular MTX polyglutamates¹² (Fig. 56.2). These polyglutamated forms are not readily transported across the cell membrane and can consequently accumulate intracellularly, with increased retention as the number of glutamate moieties increases.¹³ This modification is particularly important because polyglutamated MTX demonstrates significant increased affinity for certain folate-dependent enzymes, including thymidylate synthase, 5-aminoimidazole carboxamide ribonucleotide transformylase (AICAR transformylase), and glycylamide ribonucleotide transformylase (GAR transformylase)¹⁴ (Fig. 56.3). MTX in its ingested form is therefore essentially a prodrug, with its polyglutamated form being the active compound. The major determinants of MTX glutamate concentrations are age, renal function, and MTX dose.¹⁵

The concentration of intracellular MTX polyglutamates within red blood cells (RBCs) has been investigated as a biomarker of MTX efficacy. Although several cross-sectional studies involving RA have shown higher MTX polyglutamate levels in responders,¹⁶⁻¹⁸ in one study this relationship was not found.¹⁹ Two prospective longitudinal studies performed in patients starting MTX showed a correlation between RBC MTX polyglutamates and response,^{20,21} and in patients switching from oral to parenteral MTX, a selective accumulation of longer-chain MTX polyglutamates was demonstrated, which correlated with reduced disease activity.^{22,23} Of note, however, RBC steady-state concentrations were not achieved for at least 6 months after a change in dose.²² Determining whether MTX polyglutamate concentrations within RBCs can serve as a biomarker of MTX efficacy awaits larger, prospective, longitudinal studies. With the exception of a correlation between higher concentrations of MTX glutamate and gastrointestinal adverse events and elevated liver function test results in juvenile idiopathic arthritis,²⁴ no relationship between adverse events and MTX RBC glutamate concentrations has been found.

MECHANISM OF ACTION

MTX, an analogue of folic acid, can interfere with the ability of folic acid to serve as a cofactor for a variety of enzymes essential for purine and pyrimidine synthesis and cell replication. One of the first mechanisms proposed for MTX was inhibition of the proliferation of cells responsible for inflammation, such as lymphocytes. However, two findings have led to the suggestion of alternative hypotheses. First, the doses of MTX required to suppress inflammation are substantially lower than those used to treat

CHEMICAL STRUCTURES OF FOLIC ACID AND METHOTREXATE

Fig. 56.1 Chemical structures of folic acid and methotrexate.

TRANSPORT AND GLUTAMATION OF METHOTREXATE

Fig. 56.2 Methotrexate (MTX), an analogue of dihydrofolic acid, is a prodrug that enters cells primarily through RFC1. Once inside the cell, MTX (also known as MTXGlu1 because it is a monoglutamate) is quickly converted to its active polyglutamated forms (MTXGlu2-5) by the enzyme FPGS. This sequential addition of up to four glutamate residues prevents efflux of MTX from the cell via a number of multidrug resistance proteins belonging to the ABC family of efflux pumps. Glutamation can be reversed by GGH. ABC, adenosine triphosphate (ATP)-binding cassette; FPGS, folypolyglutamate synthase; GGH, γ -glutamyl hydrolase; RFC1, reduced folate carrier 1. (Adapted from Stamp LK, Roberts RL. Effect of genetic polymorphisms in the folate pathway on methotrexate therapy in rheumatic diseases. *Pharmacogenomics* 2011;20:1449-63.)

malignant proliferative disorders. Second, folic acid supplementation can reverse the gastrointestinal and hepatic toxicities, which are probably secondary to the antiproliferative effects of MTX, but not the therapeutic effects, which are dependent on the antiinflammatory effects of MTX.²⁵

One alternative mechanism for the antiinflammatory actions of MTX has gained favor. MTX polyglutamates bind AICAR transformylase, which leads to increased levels of AICAR, an inhibitor of adenosine monophosphate (AMP) deaminase, and AICAR's dephosphorylated metabolite AICARiboside, an inhibitor of adenosine deaminase (Fig. 56.4). This inhibition increases levels of intracellular AMP and adenosine, as well as levels of

extracellular adenosine that will bind to cell-surface receptors.²⁵ Adenosine A_{2A} receptors are expressed on T cells, natural killer cells, monocytes, macrophages, and neutrophils and can therefore dampen inflammation by a variety of mechanisms, including suppression of T-cell activation and cell-mediated cytotoxicity, inhibition of the neutrophil oxidative burst, and suppression of nuclear factor- κ B and its downstream effects.²⁶ Major support for this hypothesis comes from animal models of inflammation in which adenosine receptors are blocked or deleted.²⁷ Because caffeine is a poorly selective adenosine receptor antagonist, the role of caffeine in abrogating the effects of MTX have been studied to lend support to the adenosine hypothesis *in vivo* in humans. Although initial studies in RA showed diminished effects of MTX in patients with high caffeine intake,²⁷ a larger prospective trial did not show any association between caffeine intake and MTX efficacy.²⁸ Patients with inflammatory arthritis treated with MTX (15 mg/wk), however, showed enhanced dipyridamole-induced vasodilation, an effect dependent on extracellular adenosine levels.²⁹

Other hypotheses to explain the immunosuppressive effects of MTX have been suggested and continue to be explored. For example, it was recently shown that MTX can increase the sensitivity of a cultured T-cell line to apoptosis via a Jun N-terminal kinase (JNK)-dependent mechanism.³⁰

EFFICACY IN RHEUMATOID ARTHRITIS

Initial use

The efficacy of aminopterin, the parent compound of MTX, in managing RA was first reported in 1951 when five of six patients treated with the drug at 1 to 2 mg/day demonstrated decreased joint pain and swelling.³¹ Subsequently, several positive open-label studies of weekly MTX were conducted in RA patients.³² In the 1980s, short-term placebo-controlled trials reported significant improvement with low-dose weekly MTX.³² A flare of arthritis was observed when MTX was stopped after short-term therapy (12 weeks)³³ or after longer-term therapy (36 months).³⁴ This flare generally occurred 4 to 6 weeks after stopping MTX.^{33,34}

Efficacy compared with nonbiologic DMARDs

MTX has the same or greater efficacy than most other synthetic DMARDs, including azathioprine, gold salts, and auranofin.³² For example, the American College of Rheumatologists 20% improvement (ACR20) response as calculated in a *post hoc* analysis of the MTX versus auranofin study³⁵ reported that an ACR20 response was achieved in approximately 68% of patients with MTX (maximum dose, 15 mg/wk) and in 30% with auranofin.³⁶ MTX was superior to leflunomide in improving disease activity measures after 1 year and radiographic progression after 2 years.³⁷ In most of these early comparison studies the maximum dose of MTX was 15 mg/wk. Intraarticular MTX is not effective in RA.³⁸

Efficacy compared with biologic DMARDs

MTX has been the active comparator in studies of biologic response modifiers. Inhibitors of tumor necrosis factor- α (TNF- α) have been evaluated against and in combination with MTX. In most of these studies the MTX dose was increased to 20 mg/wk. In a 24-month trial of etanercept versus MTX (7.5 mg escalating to 20 mg weekly) in patients with early RA, MTX was less effective than etanercept during the first 4 months of therapy but achieved efficacy similar to that of etanercept thereafter. At 12 months, an ACR20 response was seen in 72% with etanercept versus 65% with MTX. In another trial comparing etanercept, MTX, and the combination (TEMPO), an ACR20 response at week 52 was noted in 75% with MTX, in 76% with etanercept, and in 85% with the combination.³⁹ In patients with early (<2 years) RA, remission according to the 28-Item Disease Activity Score (DAS28) at 52 weeks was seen in 50% with etanercept plus MTX versus 28% with MTX therapy alone.⁴⁰ In another early RA study, escalation of MTX dosages to 20 mg/wk achieved an ACR50 response in more than 35% of patients.⁴¹ These studies have provided excellent data on the efficacy of MTX monotherapy, with ACR20 responses being achieved in 54% to 73% of patients (Table 56.1).³⁹⁻⁴⁴ In most of the direct comparison studies of MTX and biologic agents, MTX achieved a similar clinical response as biologics over time. Only in the tocilizumab monotherapy study did the biologic achieve a better response than MTX,⁴³ with an ACR20/50 response at week 24 being achieved in 69.9%/44% of patients with tocilizumab versus 52.5%/34% with MTX. Even though in some patients an initial response was noted as soon as 3 to 6 weeks after starting MTX therapy, a plateau in effect is not generally observed until after 12 to 16 weeks.

Fig. 56.3 MTX, an analogue of folic acid, can interfere with the ability of folic acid to serve as a cofactor for enzymes that are critical to purine and pyrimidine synthesis and cell replication. AICAR, 5-aminoimidazole-4-carboxamide ribonucleotide; AICAR T'ASE, AICAR transformylase; DHFR, dihydrofolate reductase; dTMP, deoxythymidine monophosphate; dUMP, deoxyuridine monophosphate; FAICAR, 10-formyl AICAR; FPGS, folypolyglutamate synthase; IMP, inosine monophosphate; MTHFR, methylene tetrahydrofolate reductase; MTX, methotrexate; MTX GLU, methotrexate polyglutamate; RFC1, reduced folate carrier 1; THF, tetrahydrofolate; TS, thymidylate synthase. (Adapted from Cronstein BN. Low-dose methotrexate: a mainstay in the treatment of rheumatoid arthritis. *Pharmacol Rev* 2005;57:163-72.)

Fig. 56.4 Polyglutamate methotrexate inhibits AICAR transformylase, thereby resulting in intracellular accumulation of AICAR, which inhibits ADA and AMP deaminase. Consequently, irreversible degradation of adenosine to inosine is inhibited, as well as the conversion of AMP to IMP. Subsequently, AMP is extracellularly converted to adenosine by the ecto-5'-nucleotidase. Efficacy in combination with nonbiologic DMARDs

The efficacy of MTX in combination with other synthetic DMARDs is variable.⁴⁵ The combination of azathioprine or auranofin with MTX was not superior to monotherapy. In patients with a suboptimal response to MTX, the addition of weekly intramuscular gold⁴⁶ or cyclosporine⁴⁷ resulted in increased efficacy. Triple therapy with MTX, hydroxychloroquine, and sulfasalazine was superior to MTX monotherapy and the combination of hydroxychloroquine and sulfasalazine.⁴⁸ MTX plus leflunomide showed increased efficacy for the combination, with an ACR20 response being achieved in 46.2% with the combination versus 19.5% with MTX alone.⁴⁹

Efficacy in combination with biologic DMARDs

The therapeutic effect is improved when anti-TNF therapy is added to background MTX, and the response is better than that with MTX or anti-TNF monotherapy.^{50,51} In the TEMPO study, the combination was more efficacious than either therapy alone, as evidenced by ACR20 responses at week 52 in 85% of patients given the combination versus 75% and 76% in the MTX and etanercept groups, respectively.³⁹ The combination was better in retarding joint damage, as assessed by the Sharp score, than was monotherapy with either drug. Greater efficacy was also observed when other biologics (i.e., rituximab, abatacept, tocilizumab) were added to MTX.⁵²⁻⁵⁴

Effect on structural damage

MTX slows the radiographic progression of RA.³² In one trial comparing MTX with the combination of etanercept and MTX for early RA, no progression was seen in 59% of the patients treated with MTX monotherapy⁴⁰; in addition, in an infliximab study, no progression was seen in 39% of the patients receiving MTX monotherapy.⁵⁵ Even though the radiographic effect is not as great as with the biologics, MTX can reduce and even halt radiographic progression in some patients.

Long-term studies

Long-term prospective studies show sustained effects on disease activity and reduction of radiographic progression. A cohort of 26 RA patients receiving MTX therapy was prospectively monitored over a period of 132 months.⁵⁶ For the 10 patients who completed the study at 132 months, significant improvement over baseline was noted in arthritis activity, including 50% improvement in the joint pain index and joint swelling index in more than 65% of the patients. There was no significant difference, however, in improvement in clinical variables between 12 and 132 months of therapy. In another prospective cohort study, 29 patients treated with MTX were followed for 156 months.⁵⁷ After 13.3 years a sustained clinical effect was still observed with MTX.⁵⁷ A large multicenter prospective trial monitored 123 patients taking MTX for 5 years and showed significant improvement in all clinical disease variables, functional status, and erythrocyte sedimentation rate in 64% of the patients who completed this study.⁵⁸

Biomarkers of response to MTX

MTX decreases markers of inflammation, including the erythrocyte sedimentation rate and C-reactive protein (CRP). There is a rapid decrease in CRP, with an effect being noted in one study by day 3 after MTX dosing.⁵⁹

To date, no baseline parameters have been shown to predict a positive response to MTX.^{60,61} A *post hoc* analysis of the TEMPO study³⁹ reported that after 12 weeks of MTX therapy, patients who had a CRP level lower than 0.67 mg/dL and a swollen joint count of greater than 1 or a CRP level lower than 0.67 and a swollen joint of greater than 10 had the worse radiographic progression at week 52.⁶²

Effect on mortality

Reduced mortality has been observed with MTX treatment of RA. In a retrospective study of 1240 patients with RA,⁶³ 44% of the 191 deaths were due to cardiovascular causes. When a weighted Cox proportional hazards model was used to adjust for potential confounders, including measures of disease activity, the adjusted mortality hazard ratio was 0.4 (0.2 to 0.8). The hazard ratio for cardiovascular mortality was 0.3 (0.2 to 0.7) versus 0.6 (0.2 to 1.2) for non-cardiovascular-related death. A systematic review plus meta-analysis of studies of MTX for chronic inflammatory diseases (primarily RA) was performed and showed a lower risk for cardiovascular disease with MTX. MTX was associated with a 18% reduction in myocardial infarction (MI) in the 10 studies analyzed.⁶⁴ A systematic review limited to RA also suggested that use of MTX was associated with a reduced risk for cardiovascular events,⁶⁵ probably related to the antiinflammatory effects observed with MTX. A large National Institutes of Health-funded study is currently under way to determine whether low-dose MTX reduces the rate of reinfarction in non-RA patients with a history of MI.

ADVERSE EFFECTS

Common adverse effects

The most common reactions associated with low-dose weekly MTX are anorexia, nausea, vomiting, and diarrhea, as reported in 31% of 3463 patients in a systematic literature review of 21 prospective studies⁶⁶ (Table 56.2).⁶⁷⁻⁷² Most of these reactions occurred shortly after initiation of MTX and were mild, although in one review 2.5% of patients discontinued MTX therapy.⁶⁷ In this same group of patients, stomatitis occurred in 6% and alopecia in 1%.⁶⁷ Folic acid or folinic acid can reduce many of these toxicities. Hematologic abnormalities were found in 5% of patients in the systematic review and included leukopenia (most common), anemia, and thrombocytopenia.⁶⁶ Risk factors for MTX-induced hematologic toxicity include drug overdoses, incorrect administration such as daily dosing, renal insufficiency, dialysis, hypoalbuminemia, and concomitant drugs such as trimethoprim-sulfamethoxazole. Folic acid and folinic acid therapy, laboratory monitoring, and patient education can reduce the risk of toxicity.

Hepatic toxicity

MTX liver toxicity was well known because of the experience with MTX in patients with psoriasis, in whom severe liver disease was reported in the 1970s and 1980s. The spectrum of liver injury ranges from asymptomatic elevations in serum transaminases to hepatic fibrosis and cirrhosis, with serum transaminase elevations being most frequent. The characteristic pathology seen with MTX toxicity is hepatic fibrosis and cirrhosis. This is fortunately rare in RA patients, unlike the earlier experience of MTX in those with psoriasis. Of 3808 patients reported in 27 prospective studies, an elevation in liver transaminases of up to two times the upper limit was reported in 13% of patients, and MTX was discontinued in 3.7% of these

TABLE 56.2
Adverse effects of methotrexate for rheumatoid arthritis

Adverse effect	Estimated incidence in rheumatoid arthritis
Gastrointestinal	
Anorexia, nausea, vomiting, diarrhea	10% ⁶⁷
Hematologic	
Leukopenia, anemia, thrombocytopenia	3% ^{67,68}
Hepatic	
Elevated transaminases	15% ⁶⁸
Cirrhosis/liver failure	0.1% 5-yr cumulative incidence ⁶⁹
Pulmonary	
Interstitial pneumonitis	2.1%-8% ⁷⁰
Epstein-Barr virus–associated lymphomas	Unknown
Accelerated nodulosis	8% ⁷¹
Central nervous system	
Dizziness, headache, mood alteration, memory impairment	25% ⁷²

patients.⁶⁶ In a large North America registry (CORRONA), of 1953 patients with RA treated with MTX, aspartate aminotransferase (AST) or alanine aminotransferase (ALT) increased above the upper limit of normal in 22%, and 1% had a twofold increase in these enzymes.⁷³ Independent predictors of abnormal AST values were a lack of folate supplementation and untreated hyperlipidemia.⁶⁸ Even though elevations in serum transaminases occur frequently, especially in the first 6 months of MTX therapy, serious liver disease is extremely uncommon. A case-control study of serious liver disease in RA patients taking MTX identified 24 cases of cirrhosis and liver failure with a 5-year cumulative incidence of approximately 1 in 1000 treated patients. Elevations of serum transaminases above the upper limit of normal or low serum albumin was observed in the patients in whom serious liver disease developed versus the matched control group. Serial elevations in serum AST correlate with progression of histologic abnormalities.⁷⁴ The ability to use abnormal liver test results to predict pathology led to the recommendation for regular monitoring of serum transaminases and albumin. Late age at first use of MTX and duration of MTX therapy are independent predictors of serious liver disease.⁶⁹ The frequency of liver disease is lower in patients with RA than in those with psoriasis. Reasons for the higher rate in psoriasis could include higher alcohol consumption, higher mean body index with fatty liver disease, and higher doses of MTX.

A potentially serious complication can occur when MTX is used in patients infected with hepatitis B or C virus. Development of fulminant hepatitis after MTX withdrawal has been observed. Reactivation of the immune system by discontinuation of MTX is postulated as the cause.⁷⁵

Pulmonary toxicity

MTX can rarely cause lung injury, which is generally acute interstitial pneumonitis. In a systematic review of 3463 patients, pneumonitis was reported in 0.43%.⁶⁷ A retrospective combined cohort review and literature review identified 29 patients who had probable or definite MTX-related lung injury. Clinical features included shortness of breath (93%), cough (82%), and fever (69.0%) and occurred after a mean duration of MTX treatment of 78.6 weeks; however, 48% of the patients had been taking MTX for less than 32 weeks. Five patients died, and recurrent lung toxicity developed in four of six patients retreated with MTX.⁷⁶ A case-control study of patients reported that the strongest predictors of MTX-associated lung injury were older age, diabetes, rheumatoid pleuropulmonary involvement, previous use of DMARDs, and hypoalbuminemia.⁷⁷

Vaccination

In patients with RA and spondyloarthritis, treatment with MTX was a negative predictor of antibody response to the 7-valent pneumococcal vaccine.⁷⁸ However, a retrospective study found that patients with RA treated with MTX who received Pneumovax were protected from pneumonia when compared with those who had not been vaccinated.⁷⁹

Other adverse effects

Other adverse events seen with MTX include opportunistic infections such as *Pneumocystis carinii* pneumonia and herpes zoster infection, accelerated

nodulosis,⁷¹ gynecomastia, rashes including photosensitivity reactions, fever and a flulike illness, and nonspecific central nervous system effects such as dizziness, headache, mood alteration, and memory impairment.⁷² Fatigue is one of most common reasons that patients stop taking MTX—folinic acid may reduce fatigue.

An increased risk for melanoma (standardized incidence ratio, 3.0) has been observed in RA patients receiving MTX as compared with a normal population.⁸⁰ In general, an increase in other solid tumors is not associated with use of MTX based on the experience with high-dose MTX for malignancy or low-dose MTX for psoriasis. A higher rate of lymphoma was not observed in RA patients treated with MTX therapy alone versus RA patients never exposed to MTX therapy.⁸¹ There is increased risk for rare Epstein-Barr virus–associated lymphomas,⁸² which may occasionally regress with discontinuation of MTX.⁸³

Teratogenicity

MTX is a known teratogen that leads to multiple congenital abnormalities, especially of the nervous system (called the “aminopterin syndrome”), and higher-dose MTX is used to induce abortion. Even low-dose MTX can lead to fetal abnormalities.⁸⁴ MTX is labeled category X by the Food and Drug Administration. The sponsor package insert recommends that the use of MTX be stopped at least one menstrual cycle before attempting conception, but many rheumatologists recommend stopping it 3 months before attempting conception. There are few data to determine which recommendation is correct. MTX should not be used during lactation because the drug can be excreted in breast milk. In males with psoriasis, a reversible decrease in sperm count was seen. The package insert recommends that males stop taking MTX 3 months before attempting conception, but no firm data are available to support this recommendation.

FOLIC ACID SUPPLEMENTATION

To reduce the adverse effects of MTX such as nausea, diarrhea, stomatitis, hair thinning, fatigue, headaches, and hematologic toxicity, folic acid or folinic acid (leucovorin) is coadministered. Folic acid (5 mg or 27.5 mg each week) decreased MTX toxicity without reducing the efficacy of MTX in a randomized study.⁸⁵ Folic acid 1 mg/day or folinic acid 2.5 mg/wk reduced the incidence of elevated liver enzyme levels and decreased toxicity-related discontinuation but had no effect on gastrointestinal side effects. The mean dosages of MTX at the end of this 48-week study were higher in the folic acid and folinic acid groups than in the placebo group, thus suggesting that higher doses of MTX might be necessary for the same clinical effect.⁸⁶ Folinic acid (up to 30 mg/wk), as opposed to placebo, taken 24 hours after the MTX dose led to fewer adverse effects but no difference in disease activity when compared with placebo.⁸⁷ In contrast, in another placebo-controlled trial in which leucovorin (15 mg) was given 2 hours after MTX, the clinical and laboratory indices of disease worsened in the leucovorin group,⁸⁸ thus suggesting that the timing of folinic acid administration is probably important. Folinic acid should be taken 8 to 24 hours after MTX so that it does not block the efficacy of MTX but remains effective in reducing side effects.

PHARMACOGENOMICS

Although MTX is generally well tolerated, some patients experience adverse effects, and occasionally these are serious. In addition, even though MTX is efficacious in many patients, some patients do not respond. Therefore, ideally only patients who will tolerate and benefit from MTX should be treated. Because the critical proteins controlling the function and metabolism of MTX are known, it has been possible to study polymorphisms in some of these proteins to determine whether they influence the drug's effects.

The best-studied polymorphisms are in the methylenetetrahydrofolate reductase (*MTHFR*) gene. *MTHFR* is a critical enzyme associated with the regeneration of 5-methyltetrahydrofolate from 5,10-methylenetetrahydrofolate. 5-Methyltetrahydrofolate contributes a methyl group to homocysteine for regeneration of methionine, and deficiency can lead to hyperhomocysteinemia and methionine deficiency. More than a dozen *MTHFR* gene polymorphisms have been described, and two functional polymorphisms, 1298A→C and 677C→T, have been studied to determine whether they can influence patient response to MTX. Results have been conflicting, and currently there is no definitive evidence that these polymorphisms can predict MTX response or toxicity in patients with RA.⁸⁹ Many other polymorphisms in genes that encode proteins that control folate metabolism, MTX glutamation and transport, and adenosine metabolism

have been studied, but the results have been contradictory.⁸⁹ Understanding of the pharmacogenetics of MTX for RA awaits large statistically powered studies of functional polymorphisms.

USE OF METHOTREXATE FOR RHEUMATOID ARTHRITIS: RECOMMENDATIONS

MTX is usually started at a dose of 7.5 to 10 mg/wk, with escalation every 4 to 8 weeks until disease activity is controlled. The therapeutic dose generally ranges between 15 and 25 mg/wk. After the therapeutic dose is reached, it usually takes 4 to 6 weeks for a clinical effect to be noted. We typically start MTX at a dose of 10 mg/wk, but some clinicians start at 15 mg/wk. After 4 weeks, the dose is increased to 20 mg/wk unless toxicity is present. A systematic review supports monthly dose escalation.³ If a significant clinical effect has not been achieved, the dose can be increased to 25 mg and administered by subcutaneous injection. It is important to maximize the dose of MTX to achieve the greatest efficacy. The maximum dose of oral MTX is generally 20 to 25 mg/wk. MTX can be administered subcutaneously to patients with gastrointestinal intolerance or to nonresponders, with a predicted higher bioavailability than the with oral dosing. Splitting oral MTX (25 mg) into two divided doses taken on the same day improves bioavailability, but whether this provides the same efficacy as subcutaneous therapy is not known. The dose of MTX may be decreased over time in patients with an impressive clinical response, but most require ongoing therapy. Discontinuation of MTX is generally associated with a flare of arthritis 4 to 6 weeks after stopping the drug. Treatment with at least 1 mg of folic acid each day is used to reduce side effects. If adverse effects occur, folic acid should be increased to 2 mg/day. Outside the United States the folic acid dose is usually 5 mg 5 to 6 days per week. If side effects continue despite folic acid, folinic acid (leucovorin) beginning at 5 mg/wk should be used. The dose of leucovorin can be escalated to block side effects and should be given 8 to 24 hours after MTX. If administered within 8 hours of MTX, leucovorin may block the efficacy of MTX.

Patients should be aware of the adverse event profile. In general, MTX should be withheld during infections. We also withhold it the week of surgery and the first postoperative week, but this is not based on trial data. The ACR issued a consensus statement in 1994 that provided guidelines for monitoring liver toxicity (Box 56.1).⁹⁰ Although the 1994 statement recommends that AST, ALT, and albumin levels be monitored at intervals of every 4 to 8 weeks, a recent consensus statement recommends monitoring every 8 to 12 weeks after 3 months and every 12 weeks after 6 months of therapy.⁹¹ Routine surveillance liver biopsies are not recommended for RA patients taking traditional doses of MTX. However, biopsy should be performed in patients with persistent abnormalities on liver blood tests, defined as elevations in AST on 5 of the 9 determinations within a 12-month interval (6 of 12 if tests are performed monthly) or a decrease in serum albumin below the normal range.⁹⁰

Laboratory monitoring should be done on a regular basis. We monitor liver blood test results, creatinine level, and the complete blood count every 4 to 8 weeks, which is more conservative than the most recent recommendations.⁹¹ Patients should receive routine vaccinations, including influenza and pneumococcal vaccine, but should not receive live vaccines while taking MTX. MTX may impair antibody response to the pneumococcal vaccine, so to maximize the effect, the vaccine should be administered before starting MTX.⁷⁸ We recommend restricting the use of alcohol. Women of childbearing

potential must use birth control while taking the drug. An *ad hoc* group of international rheumatologists met to review the existing literature and published their own set of recommendations on the use of MTX for RA.⁹²

METHOTREXATE FOR OTHER RHEUMATIC DISEASES (Table 56.3)

Psoriatic arthritis

Although MTX is commonly used as a first-line agent for psoriatic arthritis, data supporting its efficacy for this disease are minimal, including several retrospective and observational studies; underpowered, double-blind, placebo-controlled trials; and studies using a maximum MTX dose of 15 mg/wk.¹⁰³ The current guidelines for monitoring hepatic toxicity when MTX is used for psoriasis have been modified by the National Psoriasis Foundation Consensus Conference.¹⁰⁴ In patients at low risk for liver disease, the guidelines no longer recommend routine surveillance liver biopsies but rather laboratory monitoring and following of the 1994 ACR guidelines.⁹¹ In high-risk patients, defined as those with diabetes, obesity,

BOX 56.1 RECOMMENDATIONS FOR MONITORING HEPATIC SAFETY IN PATIENTS WITH RHEUMATOID ARTHRITIS (RA) RECEIVING METHOTREXATE (MTX)

- A. Baseline
 1. Tests for all patients
 - a. Liver blood tests (aspartate aminotransferase [AST], alanine aminotransferase [ALT], alkaline phosphatase, albumin, bilirubin), hepatitis B and C serologic studies
 - b. Other standard tests, including complete blood cell count and serum creatinine
 2. Pretreatment liver biopsy (Menghini suction-type needle) only for patients with
 - a. Previous excessive alcohol consumption
 - b. Persistently abnormal baseline AST values
 - c. Chronic hepatitis B or C infection
- B. Monitor AST, ALT, albumin at 4- to 8-week intervals
- C. Perform liver biopsy if
 1. Five of 9 determinations of AST within a given 12-month interval (6 of 12 if tests are performed monthly) are abnormal (defined as an elevation above the upper limit of normal)
 2. There is a decrease in serum albumin below the normal range (in the setting of well-controlled rheumatoid arthritis)
- D. If results of liver biopsy are
 1. Roenigk grade I, II, IIIA, resume MTX and monitor as in B, C1, and C2 above
 2. Roenigk grade IIIB or IV, discontinue MTX
- E. Discontinue MTX in patients with persistent liver test abnormalities, as defined in C1 and C2 above, who refuse liver biopsy

■ TABLE 56.3
Use of methotrexate for other diseases

Disease	Trial design	MTX dose (mg/wk)	Response	Reference
Ankylosing spondylitis	RCT	7.5-10	Not effective for spine disease	93
Felty syndrome	Case series	7.5-12.5	Increase in WBC count	94
ANCA vasculitis	Open and RCT	20-25	Noninferior to Cytoxan. As effective as azathioprine	95-97
PMR/GCA	RCT	7.5-15	Modest effect in PMR/GCA	98, 99
Myositis	Open	10-20	No RCT but consensus acceptance for myositis	100
Lupus	Open, RCT	15-20	Positive effects on joints and skin	101
CPPD	Open	5-10	Positive report	102

ANCA, antineutrophil cytoplasmic antibody; CPPD, calcium pyrophosphate dihydrate deposition disease; GCA, giant cell arteritis; MTX, methotrexate; PMR, polymyalgia rheumatica; RCT, randomized controlled trial; WBC, white blood cell.

abnormal liver test results, or significant alcohol intake, routine surveillance liver biopsies are still recommended in psoriasis patients treated with MTX.

Juvenile idiopathic arthritis

MTX is effective in various forms of juvenile polyarthritis, including oligo-articular arthritis and a subset of children with systemic juvenile idiopathic arthritis.¹⁰⁵ The dose in children, 8 to 12.5 mg/m²/wk, is higher than that used in adults. Significant additional improvement was not observed at a dose of 30 mg/m²/wk.¹⁰⁶

Other rheumatic diseases

MTX has been used for many other rheumatologic conditions, including ankylosing spondylitis, Felty syndrome, antineutrophil cytoplasmic

antibody-associated vasculitis, polymyalgia rheumatica/giant cell arteritis, systemic lupus erythematosus, scleroderma, myositis, and calcium pyrophosphate deposition disease with variable results (see Table 56.3).

CONCLUSION

MTX is now a first-line agent for the treatment of RA and is the “anchor drug” for combination therapy with other DMARDs. It has become the standard of care and the most widely used drug for the treatment of RA. When used appropriately, it has excellent efficacy and tolerability in the treatment of RA and is the DMARD to which all new therapies should be compared. The effectiveness of MTX for other rheumatic diseases still requires further study, but existing results suggest that MTX is a useful tool for the treatment of a variety of systemic rheumatic diseases.

Leflunomide

■ BOULOS HARAOU

- Leflunomide inhibits pyrimidine synthesis, resulting in blockade of T-cell proliferation.
- Leflunomide is used in patients with moderate to severe active rheumatoid arthritis with early or late disease.
- Monotherapy with leflunomide has been shown to be as effective as methotrexate and sulfasalazine in improving symptoms and signs of rheumatoid arthritis.
- Leflunomide as monotherapy results in substantial inhibition of joint damage, as assessed radiologically.
- Leflunomide provides additional benefit in patients partially responsive to methotrexate.
- Leflunomide can be safely combined with tumor necrosis factor inhibitors or rituximab.
- Leflunomide is contraindicated in patients with interstitial lung disease or methotrexate-induced pneumonitis.
- The most common adverse effects of leflunomide are gastrointestinal symptoms and hepatotoxicity.
- Combination of leflunomide with methotrexate results in a significant increase in liver enzyme abnormalities.
- Leflunomide is teratogenic in animals and is therefore contraindicated in women who may become pregnant.

CHEMICAL STRUCTURE AND MODE OF ACTION

Leflunomide, N-(4-trifluoromethylphenyl)-5-methylisoxazole-4-carboxamide ($C_{12}H_9F_3N_2O_2$), is an isoxazole derivative with immunomodulatory and disease-modifying properties in rheumatoid arthritis (RA). It is a prodrug that is rapidly converted in the submucosal wall of the intestinal tract and after first passage in the liver into its active metabolite A77 1726, a manolonitrilamide. It appears that genetic polymorphisms in CYP1A2, a cytochrome P450 isoenzyme that may play a role in this transformation, could be linked to the pharmacokinetics and toxicity of leflunomide.¹

A77 1726 inhibits dihydroorotate dehydrogenase (DHODH), a mitochondrial enzyme that is critical for the *de novo* synthesis of pyrimidines (Fig. 57.1).² It is thought that this property effectively blocks the proliferation of human lymphocytes, which are highly dependent on this pathway for nucleotide synthesis.³ This leads to an arrest in the G1/S phase of the cell cycle. The concentration of A77 1726 needed to block T-cell proliferation after mitogen stimulation varies greatly among species and can be reversed *in vitro* by the exogenous addition of uridine in a dose-dependent fashion.^{4,5} Pyrimidines are also needed by proliferating cells to form the lipids and macromolecules essential to several cell functions such as cell-cell contact, diapedesis, and intracellular signaling (Fig. 57.2). Genetic polymorphism in DHODH has also been shown to play a role in leflunomide toxicity.¹

Furthermore, DHODH may be involved in other cellular mechanisms such as B-cell proliferation and immunoglobulin synthesis.^{6,7}

In several *in-vitro* stimulated and unstimulated cell lines, A77 1726 was demonstrated to inhibit two important transcriptional factors critical to the function of cells of the immune system and inflammation^{8,9}: tyrosine kinase activity and nuclear factor κ B (NF- κ B) activation and gene expression. It seems also that A77 1726 may directly block the JAK/STAT pathway,

inhibiting the production of interleukin-17 (IL-17), an effect that is not reversed by the addition of uridine¹⁰; it was also shown to suppress IL-1 β expression and matrix metalloproteinase-1 (MMP-1) production more efficiently than dexamethasone.¹¹ On the other hand, A77 1726 did not have any effect on IL-4 production or IL-2 receptor expression.¹² After 1 year of treatment with leflunomide, RA patients showed a reduction in the levels of interferon- γ (IFN- γ) but not of IL-6, which suggests a preferential effect on T cells.^{13,14}

Leflunomide has also been shown to inhibit chemotaxis of peripheral blood neutrophils in RA patients.¹⁴ Studies of synovial tissues in RA patients receiving leflunomide revealed a reduction in synovial macrophages as well as expression of intracellular adhesion molecule 1 and vascular cell adhesion molecule 1.¹⁵ A decreased ratio of MMP-1 to tissue inhibitor of metalloproteinase 1 was also demonstrated.

In vitro, the active metabolite A77 1726 was shown to directly inhibit both the generation and the activity of osteoclasts.¹⁶ This activity seems to be independent of its inhibition of uridine synthesis or the blockade of NF- κ B.

HUMAN CLINICAL PHARMACOKINETICS

Absorption and bioavailability

After oral absorption, leflunomide is rapidly metabolized to A77 1726 within the gut wall, plasma, and liver. The active metabolite is very highly bound to plasma protein (more than 99%) and, correspondingly, has a low apparent volume of distribution. At a dose of 20 mg/day, steady state is reached in 7 weeks, and the average plasma concentration of A77 1726 is approximately 35 mg/mL. Trough plasma concentrations are linearly related to the maintenance dose of leflunomide, which indicates linear pharmacokinetics.

A77 1726 undergoes enterohepatic circulation and biliary recycling, which contributes to its long elimination half-life of approximately 2 weeks. Therefore, to achieve a steady state rapidly, administration of a loading dose followed by a lower maintenance dose has been used.

It was also shown that certain transporters may play a role in leflunomide resistance or suboptimal response. One such transporter is ABCG2, which is part of the breast cancer resistance protein (BCRP) family.¹⁷

Metabolism and elimination

Almost half of the administered dose is excreted as unmetabolized A77 1726 in the feces. Glucuronide conjugates and oxolinic acid derivatives are the principal metabolites recovered in the urine. A77 1726 is still detectable in the urine 36 days after administration of a single dose. A77 1726 readily binds to orally administered activated charcoal and even more so to cholestyramine, which enhances its elimination; these characteristics are used in clinical situations whenever toxicity is present or rapid reduction of blood levels is required.

Drug interactions

In a clinical trial in RA patients, the pharmacokinetics of A77 1726 and methotrexate were not altered by concomitant administration.¹⁸ The maximum concentration of A77 1726 after the loading and maintenance doses remained within the range seen in patients treated with leflunomide alone.

In vitro, A77 1726 is an inhibitor of CYP2C9, through which warfarin, tolbutamide, phenytoin, and several nonsteroidal antiinflammatory drugs

Fig. 57.1 Blocking of dihydroorotate dehydrogenase (DHODH), a key enzyme in the *de novo* synthesis of uridine, by leflunomide. ATP, adenosine triphosphate; CPSII, carbamoyl phosphate synthetase II.

are metabolized. However, in human *in-vivo* situations the free unbound drug is below the half-maximal inhibitory concentration (IC_{50}) for this enzyme, and no clinically significant drug interactions have been reported.

Based on recent pharmacokinetics studies in a pediatric population, the recommended daily dose of leflunomide is 20 mg for patients weighing more than 40 kg, 15 mg for those between 20 and 40 kg, and 10 mg for patients weighing less than 20 kg.¹⁹

EFFICACY

Monotherapy

Evidence from four multicenter, double-blind, randomized, controlled trials shows that leflunomide monotherapy is effective in the treatment of RA, is

Fig. 57.3 Percentage of patients treated with leflunomide, methotrexate, or placebo who met the American College of Rheumatology (ACR) response criteria for improvement of 20%, 50%, 70%, or more (ACR20, ACR50, ACR70) at 12 months. (Data from Strand V, Cohen S, Schiff M, et al. *Treatment of active rheumatoid with leflunomide compared with placebo and methotrexate.* Arch Intern Med 1999;159:2542-50.)

significantly superior to placebo, and is similar in efficacy to sulfasalazine as well as moderate-dose methotrexate.

In the initial 6-month placebo-controlled dose-ranging study involving 402 patients (with a disease duration of 8.3 years), leflunomide was evaluated in doses of 5, 10, and 25 mg preceded by a single loading dose. In this study the two highest doses proved to be most efficacious.²⁰

In a subsequent 12-month study of leflunomide therapy in 482 patients (with a disease duration of 7 years), leflunomide at a dosage of 20 mg/day (after 100-mg loading doses on days 1 to 3) was compared with methotrexate (mean dose, 13.5 mg/wk) and placebo.²¹ When the less stringent ACR20 (American College of Rheumatology 20% improvement criteria) last observation carried forward analysis was used, leflunomide was found to be associated with a response rate of 52% compared with 46% for methotrexate. Response rates for both agents were higher than in the placebo group (26%) (Fig. 57.3). Clinically meaningful and statistically significant improvements in measures of function and health-related quality of life and work productivity were seen during treatment with leflunomide compared with placebo (Fig. 57.4). Leflunomide treatment resulted in significantly greater improvement in a number of the disability and quality of life measures.²² Leflunomide and methotrexate inhibited disease progression in approximately half the patients as measured by radiographic analysis (Fig. 57.5) and resulted in statistically significantly less radiographic progression compared with placebo at 12 months.²³

Longer-term efficacy was evaluated in a 12-month extension study in which patients who completed 52 weeks of treatment were given the option of continuing therapy for an additional year.²⁴ Patients receiving both leflunomide and methotrexate showed consistent improvement in signs and symptoms as well as in measures of function and health-related quality of life over the second year. The withdrawal rate in both groups of the year 2 cohort was low (<5%).

Leflunomide (20 mg/day) was also compared with methotrexate (10 to 15 mg/wk) in a head-to-head study involving 999 patients with shorter disease duration (3.7 years).²⁵ At 52 weeks, patients were given the option of continuing double-blind therapy for an additional 52 weeks. At the end of the first year more methotrexate-treated patients met ACR20 criteria (64.3%) than leflunomide-treated patients (50.5%) (Fig. 57.6). Improvement in signs and symptoms was also greater in the methotrexate-treated group after 1 year of therapy. As in the previous study, leflunomide elicited a more rapid response to therapy. Whether the higher methotrexate response rate in this study was a result of not including a folate supplement is unclear. In the subset of patients who elected to continue therapy for a second year, the ACR20 response rates were comparable for both drugs after 2 years of therapy. Disease modification as measured radiographically was similar with both drugs at 52 weeks but was more effective with methotrexate than with leflunomide after 2 years of therapy.

Leflunomide was also compared with sulfasalazine in a 6-month placebo-controlled study of 358 patients with a disease duration of 7 years.²⁶ At

Fig. 57.6 Percentage of patients who met the American College of Rheumatology (ACR) response criteria for improvement of 20% (ACR20) after 12 and 24 months of therapy with leflunomide or methotrexate. (Data from Emery P, Breedveld FC, Lemmel EM, et al; Multinational Leflunomide Study Group. *A comparison of the efficacy and safety of leflunomide and methotrexate for the treatment of rheumatoid arthritis*. *Rheumatology* 2000;39:655-65.)

6 months, the ACR20 response rate was comparable for the groups treated with leflunomide (55%) and sulfasalazine (56%), and responses for both groups were superior to that for the placebo group (29%) (Fig. 57.7). Leflunomide demonstrated a more rapid onset of action, which was particularly evident after 1 month of therapy. At 6 months, both drugs inhibited radiographic progression to a similar extent. Patients completing the initial 6-month phase were given the option of continuing in a double-blind fashion in 12- and 24-month extension studies, with the placebo group switching to sulfasalazine. Leflunomide- and sulfasalazine-treated patients demonstrated a sustained response to 12 months, with the leflunomide cohort demonstrating a significantly greater ACR20 response rate than the sulfasalazine group at 24 months. Little disease progression, as determined radiographically, was observed at 1 year and 2 years in the cohort receiving leflunomide and in patients receiving sulfasalazine who remained on therapy (Fig. 57.8).

Combination therapy

Because methotrexate is thought to act primarily on the purine pathways of cellular metabolism whereas leflunomide inhibits pyrimidine pathways, the combination of leflunomide and methotrexate has the potential for synergy in inhibiting the proliferation of cells involved in the immune inflammatory response.

The safety, efficacy, and pharmacokinetics of combination therapy with leflunomide and methotrexate were initially evaluated in an open-label 52-week study of 30 patients who exhibited active disease despite receiving 17 mg/wk of methotrexate.¹⁸ After administration of a loading dose of 100 mg/day for 2 days, leflunomide was given in a dosage of 10 mg/day for 3 months and then increased as required to 20 mg in patients with persistently active disease.

Fig. 57.7 Percentage of patients who met the American College of Rheumatology (ACR) response criteria for improvement of 20%, 50%, or 70% (ACR20, ACR50, ACR70) after 6 months of therapy with leflunomide, sulfasalazine, or placebo. (Data from Smolen JS, Kalden JR, Scott DL, et al. Efficacy and safety of leflunomide compared with placebo and sulfasalazine in active rheumatoid arthritis: a double-blind randomized multicentre trial. *Lancet* 1999;353:259-66.)

Fig. 57.8 Mean change in Larsen score for patients treated for 6, 12, and 24 months with leflunomide, sulfasalazine, or placebo. (Data from Scott DL, Smolen JS, Kalden JR, et al. Treatment of active rheumatoid arthritis with leflunomide: two-year follow-up of a double-blind, placebo-controlled trial versus sulfasalazine. *Ann Rheum Dis* 2001;60:913-23.)

There was no significant pharmacokinetic interaction between leflunomide and methotrexate. The combination was generally well tolerated; however, liver enzyme elevations were seen in the majority of patients (63%). Efficacy measures revealed a good response, with 53% of patients achieving ACR20 criteria. Liver biopsies in three patients with elevated liver enzyme levels revealed mild (not clinically significant) hepatic fibrosis in two patients and normal findings in one patient.

The combination of leflunomide and methotrexate was subsequently evaluated in a 24-week double-blind, placebo-controlled study of 263 patients with RA who exhibited an inadequate response to methotrexate.²⁷ Leflunomide was given in a dosage of 10 mg/day (after administration of two 100-mg loading doses) for 2 months, after which the dosage could be increased to 20 mg/day. The results showed that leflunomide provided additional benefit in 51.5% of patients who showed a partial response to methotrexate alone. Elevated liver function test results were observed in 28% of patients receiving combination therapy. These data suggest that the leflunomide-methotrexate combination can be used with appropriate liver

enzyme monitoring. A 6-month open-label extension was carried out in which patients receiving the combination of leflunomide and methotrexate continued treatment, whereas patients previously given methotrexate alone now received leflunomide (in combination with methotrexate) in a dosage of 10 mg/day without a loading dose, with subsequent dose adjustment based on the patient's response.²⁸ The combination of leflunomide and methotrexate continued to provide significant therapeutic benefit, and patients switching from placebo to leflunomide showed the same magnitude of response after 6 months despite the lack of a loading dose of leflunomide (Fig. 57.9). These data suggest that, in patients with an inadequate response to methotrexate, leflunomide is effective without the use of a loading dose. Another randomized controlled trial supported the concept that the combination of sulfasalazine with leflunomide was ineffective by demonstrating no significant difference in the Disease Activity Score when sulfasalazine was added to leflunomide compared with the use of sulfasalazine alone in patients who had previously shown inadequate response to leflunomide monotherapy.²⁹ However, a trend toward a higher response was seen, and the ACR70 response rate of the group given both drugs was superior to that of the group given sulfasalazine alone. A subsequent analysis of results for 968 patients with RA demonstrated that adding leflunomide or sulfasalazine to methotrexate rather than switching to monotherapy did not result in significantly different retention rates for leflunomide or sulfasalazine. Data from a large observational database encompassing 1214 RA patients were used to evaluate the clinical outcomes of two potential strategies in patients discontinuing disease-modifying antirheumatic drugs (DMARDs) because of ineffectiveness: switching to another DMARD, and step-up combination therapy with methotrexate, sulfasalazine, or leflunomide. Retention rates for leflunomide and sulfasalazine were similar for adding and for switching.³⁰

The efficacy and safety profiles of 10-mg versus 20-mg doses of leflunomide were evaluated in a 24-week multinational, randomized, double-blind, parallel-group study of 402 RA patients.³¹ Patients receiving 10 mg of leflunomide were given one 100-mg loading dose on day 3, whereas those receiving 20 mg were given a 100-mg loading dose on days 1 to 3. The results demonstrated superiority of the 20-mg dose.

Open-label and extension studies

A 5-year open-label uncontrolled extension study demonstrated that the early efficacy of leflunomide based on ACR response rates and Health Assessment Questionnaire scores seen at 1 year was maintained for up to 5 years.³² The long-term safety profile was similar to that in previous studies. The sustainability of improvement in physical function and health-related quality of life (HRQOL) was examined in three phase 3 randomized controlled trials comparing leflunomide, sulfasalazine, and methotrexate. Over 24 months, improvements in physical function were shown to be sustained and reflected improvements in mental as well as physical domains of HRQOL.³³

Postcommercialization registries were started and observational studies conducted in several countries and were independently managed by local investigators, in most instances with financial or logistic support from the drug manufacturer. Data for one cohort of 285 patients were analyzed to determine the percentage of patients discontinuing leflunomide treatment over time compared with the percentage discontinuing treatment with other conventional DMARDs including methotrexate and sulfasalazine; leflunomide was associated with higher discontinuation rates due to toxicity but similar discontinuation rates due to lack of efficacy.³⁴

Several other open-label prospective studies have evaluated the efficacy and safety of leflunomide in real-life settings. One German study included 308 patients with early RA (disease duration of 1 year or less) who were treated for 24 weeks. All patients were eligible for leflunomide therapy according to the German prescription guidelines.³⁵ More than 50% were DMARD naive; 57% received a 3-day 100-mg loading dose, and the daily maintenance dose was 20 mg in 92% of patients. Leflunomide was administered in combination with methotrexate in 22% and in combination with another DMARDs in 5% of patients. At 6 months, 254 patients (82%) completed the study; 36.2% achieved a good EULAR response and 48.4% achieved a moderate response, with the vast majority reaching this level of response by 12 weeks. No new safety issues were raised.

A prospective postmarketing study was conducted in New Zealand and included 380 patients with long-standing RA (mean disease duration, 12.1 years); follow-up data were available for 244 patients.³⁶ The leflunomide loading dose was given to 90% of patients, and more than 80% received the 20-mg maintenance dose. Retention rates were 64% at 1 year and 49.4% at 2 years. Leflunomide was administered as monotherapy in 30%. Fifty-seven patients discontinued therapy because of adverse effects, the majority of which were gastrointestinal (49%). Seven patients required washout

Fig. 57.9 American College of Rheumatology (ACR) response rates at weeks 24 and 48 in patients receiving double-blind leflunomide (LEF) and methotrexate (MTX) from week 0 to 48 and in patients receiving placebo and methotrexate from week 0 to 24 followed by open-label leflunomide and methotrexate from week 24 to 48. (Data from Kremer J, Genovese M, Cannon G, et al. Combination of leflunomide and methotrexate [MTX] therapy for patients with active rheumatoid arthritis failing MTX monotherapy: open-label extension of a randomized, double-blind placebo controlled trial. *J Rheumatol* 2004;31:1521-31.)

procedures: two patients for Stevens-Johnson syndrome, two for diarrhea, and one each for abnormal liver function test results, skin rash, and desire to become pregnant.

The effectiveness of leflunomide was compared with that of infliximab and etanercept using survival on drug as an evaluation tool. Patients in a standardized clinical protocol were evaluated over 12 months. Patients not responding to DMARDs, including methotrexate, were treated with etanercept ($n = 184$), infliximab ($n = 223$), or leflunomide ($n = 114$). Rates of survival on drug as a percentage of the number of patients followed were 82%, 55%, and 32% at 12 months for etanercept, infliximab, and leflunomide, respectively. However, differences in patient selection and drug efficacy may have influenced the comparison between the tumor necrosis factor (TNF) blockers and leflunomide.³⁷ Similar data regarding the sustainability of leflunomide therapy were obtained in a prospective case series study in 136 patients initiating treatment with the drug. After a median follow-up of 317 days, 56% of patients receiving leflunomide withdrew from treatment, mainly because of adverse drug reactions (29%) or lack of efficacy (13%).³⁸

Combination therapy with biologic agents

The increasing use of biologic agents in RA coupled with the concept of combination therapy has resulted in increased use of a combination of leflunomide and biologic agents. All the data have been generated independently by investigators. Analyses of data from the Swiss (SCQM) and German (RABBIT) registries have compared the efficacy and safety outcomes of the combination of anti-TNF agents with methotrexate, leflunomide, or other DMARDs.^{39,40} Around 20% to 25% of patients were treated with TNF inhibitors and leflunomide compared with more than 70% who received anti-TNF agents with methotrexate. Both agents had comparable efficacy and retention rates.

More recently, an open-label prospective observational study of the random addition of an anti-TNF agent (etanercept, infliximab, or adalimumab) to either methotrexate or leflunomide in patients with inadequate response to the latter two drugs was reported.⁴¹ The 60 patients in each treatment group were assessed at 4, 12, and 24 weeks. Clinical efficacy and retention rates were comparable for the groups given methotrexate plus anti-TNF agent and leflunomide plus anti-TNF agent, with a slightly higher rate of discontinuation due to adverse effects in the leflunomide group.

The advent of biologic agents other than the TNF inhibitors has prompted interest in combining these agents, in particular rituximab, with leflunomide.⁴² The Collaborative European Registries for the Evaluation of Rituximab in Rheumatoid Arthritis (CERERRA) compared the clinical responses and safety profiles of rituximab when given in combination with methotrexate (1195 patients), in combination with leflunomide (177 patients), or as monotherapy (505 patients). More patients in the leflunomide combination group achieved good and moderate EULAR responses at 6 and 12 months and fewer patients required retreatment at 12 months than in the other two groups. Adverse events occurred in 10.2%, 13.2%, and 13.9% of patients in the rituximab plus leflunomide, rituximab plus methotrexate, and rituximab monotherapy groups, respectively.

Treatment of other rheumatologic conditions

Since the commercialization of leflunomide, clinicians in different countries have reported their independent experiences in using leflunomide for the treatment of other rheumatologic conditions in addition to rheumatoid arthritis. Although juvenile idiopathic arthritis is not an official indication for leflunomide therapy, its efficacy compared with methotrexate in treating this condition was demonstrated in a small randomized trial.⁴³ Leflunomide and methotrexate were dosed based on patient weight, with a full dose given to those weighing more than 40 kg. Methotrexate had numerically superior efficacy, with 89% of those in the methotrexate-treated group achieving a ACR Pedi30 response at 16 weeks versus 68% in the leflunomide group. With both drugs improvement was maintained to 48 weeks, and tolerability was comparable.

A retrospective analysis of the use of leflunomide was conducted that involved 48 patients with juvenile idiopathic arthritis who had switched from methotrexate, primarily because of adverse events, and an additional 10 patients in whom leflunomide was added to ongoing methotrexate therapy.⁴⁴ About 30% of patients attained remission; leflunomide was discontinued in 15 patients, in the majority (13) because of adverse effects.

The use of leflunomide in psoriatic arthritis has been evaluated in a large multicenter international study funded by the manufacturer.⁴⁵ In a 24-week controlled study of 188 patients with psoriatic arthritis, a modified ACR20 result was achieved in 36% of leflunomide-treated patients at 24 weeks compared with 20% in the placebo group. Fifty-nine percent of the leflunomide-treated patients compared with 30% of the placebo-treated patients achieved a psoriatic arthritis response (as judged by PsARC). The effect on psoriasis was also mild, with 17% of patients receiving leflunomide and 7% of those given placebo achieving a significant clearing of skin disease (as measured by PASI-75).

Encouraging results have been observed with leflunomide in combination with methotrexate or rituximab in antineutrophil cytoplasmic antibody-associated granulomatous vasculitis,^{46,47} Takayasu arteritis,⁴⁸ and sarcoidosis.⁴⁹ It was found to be ineffective in a pilot study in patients with primary Sjögren syndrome and a randomized controlled trial in patients with ankylosing spondylitis.

SAFETY AND TOLERABILITY

In clinical trials involving a total of 1339 patients treated with leflunomide monotherapy, the frequency of adverse effects and the safety profile of leflunomide are in general similar to those of moderate-dose methotrexate and sulfasalazine. However, the adverse effects tend to persist longer with leflunomide, even with dose reduction or discontinuation of therapy, because of the long half-life of the drug. The most common reported adverse effects are the following:

- **Gastrointestinal effects:** Gastrointestinal symptoms include diarrhea, dyspepsia, nausea, vomiting, and abdominal pain. Diarrhea is

generally mild to moderate and usually occurs within the first 3 months. In approximately 30% of patients, diarrhea resolves within 1 week, but in about 35% the symptoms persist for longer than 1 month. Nausea and vomiting are usually transient. Significant weight loss has also been reported in 7% of 70 patients beginning leflunomide therapy.⁵⁰ In a retrospective chart review encompassing 108 patients with inflammatory arthritis treated at UK centers with a combination of leflunomide and methotrexate, at a median of 24.5 months after initiation of therapy 51% of patients were still taking the drug combination. The most common reasons for discontinuation were nausea, vomiting, diarrhea, and abnormal liver function test results.⁵¹

- **Neurologic effects:** Nervous system effects of leflunomide include headache, dizziness, and paresthesia. The central nervous system adverse effects are usually mild to moderate and are not commonly a cause for stopping the drug. Case reports of peripheral neuropathy submitted to the U.S. Food and Drug Administration (FDA) in association with leflunomide have been reviewed.⁵² In the 80 reported cases, symptoms began after a mean of 6 months of treatment. Electrodiagnosis was consistent with distal axonal, sensory, or sensorimotor polyneuropathy in most patients. Patients withdrawing from leflunomide within 30 days were more likely to show improvement. In a study to monitor potential clinical neurotoxicity in 113 leflunomide-treated patients, eight incident cases of peripheral neuropathy and two cases of worsening of preexisting neuropathy were diagnosed by nerve conduction studies (incidence, 9.8%).⁵² Compared with patients not receiving leflunomide, patients receiving leflunomide were older (mean age, 69), more often diabetic (30%), and more often treated with potentially neurotoxic drugs (20%). At least one risk factor was found in 50% of patients with neuropathy (positive predictive value, 56%; negative predictive value, 96%). These results suggest the need for careful monitoring of the patient's neurologic status during leflunomide treatment. Patients have been reported to experience stabilization symptomatically and electrophysiologically on cessation of the drug.
- **Cardiovascular effects:** Hypertension is the most common cardiovascular effect of leflunomide. Data from clinical trials suggest that aggravation of existing hypertension is more likely to be a problem with leflunomide than new-onset hypertension.
- **Infection:** Clinical trials did not show a higher incidence of infection in patients receiving leflunomide than in patients receiving placebo. However, leflunomide is not recommended for patients with some immunodeficiency, substantial impairment of bone marrow function, or serious infections (i.e., those requiring intravenous antibiotics or hospitalization). If infection occurs in patients receiving combination therapy with another immunosuppressant such as methotrexate or corticosteroids, early and vigorous treatment should be considered. Leflunomide should be discontinued in the event of a serious infection and a washout procedure should be initiated. No cases of disseminated fungal or viral disease or opportunistic infections have been reported during clinical trials with leflunomide. A retrospective study of 201 patients revealed a higher risk of postoperative wound-healing complications after elective orthopedic surgery in patients receiving leflunomide therapy (40.6%) than in patients receiving methotrexate (13.6%) ($P = .01$).⁵³ Although it was recommended to interrupt leflunomide treatment preoperatively in this group of patients, the long half-life of leflunomide makes that impractical.
- **Cutaneous effects:** Leflunomide was associated with a higher rate of skin reactions compared with placebo in clinical trials, with an overall incidence of rash of 9.9%. Most rashes occurred between the second and fifth months of treatment and resulted in discontinuation of therapy in 1.3% of patients. Rare cases of Stevens-Johnson syndrome and toxic epidermal necrolysis have been reported. In all cases, patients were concurrently receiving other medication known to be associated with these skin lesions. Any suspicion of either of these conditions necessitates discontinuation of leflunomide and initiation of a cholestyramine washout procedure. Under these circumstances, reexposure to leflunomide is contraindicated. Alopecia was observed with low frequency and was reversible on discontinuing the drug. A small percentage of patients (fewer than 1.0%) withdrew because of alopecia. Mouth ulcers occurred at the same frequency as with placebo in these trials.
- **Respiratory effects:** Interstitial lung disease (ILD) has been reported in patients receiving leflunomide.⁵⁴ Baseline pulmonary disease and/or abnormal findings on chest radiographs or computed tomographic scans were observed in 69% of 29 patients before initiation of leflunomide. Prior methotrexate therapy was reported in 42% of patients. Forty-one percent of patients died. Most patients initially seek

treatment for acute pneumonitis, but a number of patients have slowly progressive ILD at presentation. In one report,^{54a} the mean duration of leflunomide treatment was 14.5 months before the onset of ILD. In another report,^{54b} pneumonitis occurred 12 to 20 weeks after the addition of leflunomide to methotrexate. A significant mortality rate, as high as 30%, has been associated with this pulmonary complication. Histologic findings include a mosaic pattern of acute and organizing diffuse alveolar damage. Treatment with early withdrawal of leflunomide, high-dose corticosteroids, and cholestyramine has been shown to be effective in some patients.⁵⁵ A population-based epidemiologic study using a claims database encompassing 62,734 RA patients demonstrated that the increased risk of ILD was associated with leflunomide use in patients with a history of methotrexate use or preexisting ILD, with a relative risk (RR) of 2.6 (95% confidence interval [CI], 1.2 to 5.6).⁵⁶ In patients with no previous methotrexate use or history of ILD the risk of ILD was not elevated (RR, 1.2; 95% CI, 0.4 to 3.1). The results were thought to be a consequence of the channeling of high-risk patients to leflunomide therapy. A postmarketing surveillance study of leflunomide use in 5054 Japanese patients was recently reported.⁵⁷ Sixty-one patients were reported to have lung injury with one third dying of it. Risk factors included preexisting ILD, use of a loading dose, history of smoking, and low body weight (40 kg or less). Recently, a review of the English literature found 32 cases of leflunomide-associated ILD, with the majority (82%) presenting within the first 20 weeks of therapy, and found the same risk factors of preexisting ILD or methotrexate lung toxicity; these two conditions should be considered contraindications to leflunomide use.⁵⁸ It seems that Japanese patients are more prone to such complications than are Western patients.

- **Hematologic effects:** Rare cases of pancytopenia have been observed in postmarketing experience, primarily in patients with known risk factors for blood dyscrasias; many cases were confounded by concomitant use of other medications. Significantly, leflunomide was not associated with an increased risk of lymphoproliferative disorders, which occurred at a frequency of 0.2% in around 2077 patient-years of exposure. This frequency was in line with the expected rate of lymphoproliferative disorders in RA of 0.2%. No increase in the incidence of malignancies has been demonstrated, with a reported rate of 1.3% for leflunomide compared with 1.2% for placebo.
- **Teratogenicity:** Leflunomide is teratogenic in animals and therefore is contraindicated during conception and pregnancy. The Organization of Teratology Information Specialists (OTIS) reported on the outcomes of 64 pregnancies in Canada and the United States in women exposed to leflunomide compared with outcomes in 108 women exposed to other DMARDs and 78 healthy controls.⁵⁹ There were 56 live births in the leflunomide group, comparable to the rates in the other two groups. Nearly all the women (95.3%) underwent at least one course of cholestyramine washout, and in a metabolite level below 0.02 mg/mL was documented. Birth outcomes were similar across the three groups.

Laboratory tests

The incidence of elevation of liver enzymes—alanine aminotransferase (ALT) and aspartate aminotransferase (AST)—with leflunomide therapy is similar to that observed with moderate-dose methotrexate therapy in patients receiving folate supplementation. ALT elevations of less than three times normal are usually reversed without discontinuation of leflunomide and may decrease with continued therapy or with dose reduction. Elevations of more than three times normal also reverse with dose reduction or discontinuation. Persistently elevated liver function test results should not be tolerated and should prompt drug withdrawal. Cholestyramine should be administered to patients with persistent elevation above three times normal levels despite withdrawal. A cholestyramine washout of 8 g three times daily for 11 days is generally adequate. Liver function abnormalities are generally asymptomatic and are not associated with decreased serum albumin level or prolonged prothrombin time. Because the active metabolite is cleared by the liver and biliary system, leflunomide is contraindicated in patients with impaired liver function. Liver function should be monitored on a regular basis.

Studies of combination therapy with leflunomide and methotrexate have found increased hepatotoxicity. In the larger study by Kremer and colleagues,²⁷ nearly 30% of patients exhibited an increase in AST or ALT levels at some time during the 6-month study, but only 1.5% and 3.8% demonstrated a threefold elevation of AST and ALT, respectively. The higher

incidence of elevated liver enzyme levels when leflunomide is combined with methotrexate for treatment of RA and psoriatic arthritis was confirmed in the analysis of the Consortium of Rheumatology Researchers of North America (CORRONA) database⁶⁰; a relation to the dose of methotrexate was also documented. The substantial proportion of patients who exhibit liver function abnormalities with the leflunomide-methotrexate combination suggests a need for careful monitoring of liver function with this combination. The data concerning serious liver toxicity reported to date for this combination (see earlier) have emphasized this requirement. A postmarketing report from the European Agency for the Evaluation of Medicinal Products detailed the experience in leflunomide-treated RA patients with a total drug exposure of 104,000 patient-years. The report described 296 cases of hepatic abnormality, including 129 cases of serious liver disease. The 296 cases included 232 patients with liver function abnormalities, 2 with cirrhosis, 15 with liver failure, and a total of 15 deaths. Most of the liver abnormalities occurred within the first 6 months of treatment without predilection for age or gender. Most of the patients with serious hepatotoxicity were also taking another potentially hepatotoxic drug (e.g., nonsteroidal antiinflammatory drugs and/or methotrexate) and had one or several comorbidities (including alcohol abuse; hepatitis A, B, and C; ILD; renal insufficiency; autoimmune liver disease; and pancreatitis).

After an extensive review of available data from clinical trials and several medical databases and postmarketing surveillance reports, the FDA Advisory Committee concluded that serious hepatotoxicity such as hepatocellular jaundice and acute liver failure is rare.⁶¹ Postmarketing surveillance spontaneous reporting by the FDA revealed that hepatic failure occurred with an incidence of 14 per 100,000 patient-years, similar to that observed with other DMARDs.⁶² A large claims database study demonstrated comparable results.

Treatment-related anemia was not observed with leflunomide. Some patients experienced transient reductions in white blood cell count without sustained leukopenia, as well as transient thrombocytopenia. In patients with recent or concurrent treatment with immunosuppressive drugs or with bone marrow toxicity potential or hematologic abnormalities, frequent hematologic monitoring should be performed. No clinically significant effect of leflunomide on levels of plasma electrolytes, total protein, creatinine, bilirubin, alkaline phosphatase, glucose, cholesterol, or triglycerides has been noted. A reduction in serum uric acid level was observed in 30% of treated patients, with an average reduction of 60 mm/L during therapy that was not associated with reduced calcium phosphate or bicarbonate levels. Uricosuria was related to inhibition of uric acid reabsorption. Renal function as determined by serum creatinine and urea levels was unaffected. However, given that leflunomide is partially eliminated by the kidney, it should be used with caution in patients with mild renal insufficiency. Leflunomide is contraindicated in patients with moderately severe renal impairment. Several case reports have addressed a potential interaction between leflunomide and warfarin. Such an interaction was at least partially responsible for an increase in international normalized ratio in a patient with a previously stable ratio. In patients taking both drugs clinicians should increase their frequency of monitoring of the international normalized ratio and adjust the warfarin dosage accordingly.

PRESCRIBING TIPS

Leflunomide is indicated for patients with moderate to severe active RA in both early and late disease. Because of its long half-life, leflunomide therapy

has been initiated with a loading dose of one 100-mg tablet/day for 3 days. However, because of toxicity concerns, many rheumatologists have stopped using the loading dose. Generally, a daily maintenance dosage of 10 to 20 mg/day is used. If dosing at 20 mg/day is not well tolerated clinically, the dosage may be decreased to 10 mg/day. In patients in whom the risk of toxicity is greater (e.g., those who are taking leflunomide in combination with methotrexate or those who are elderly) the maintenance dosage may be initiated at 10 mg/day for 2 months with a dose escalation to 20 mg if there is an inadequate response. Caution should also be exercised by using the lowest possible dose of methotrexate. As noted earlier, for patients not requiring a rapid response to therapy, consideration should be given to initiating therapy without a loading dose.

Before initiation of the drug a complete blood cell count, including a differential white blood cell and platelet count, and liver function tests, including AST and ALT levels, must be performed. According to the product monograph, a complete blood cell count and liver blood tests should also be performed every 2 weeks for the first 6 months and then every 8 weeks thereafter. More frequent early monitoring might be done if the drug is used in combination with methotrexate.

Patients experiencing a serious adverse effect of leflunomide should undergo a washout with cholestyramine (8 g three times daily) or activated charcoal (50 g four times daily) for 11 days. The metabolite of leflunomide, A77 1726, is not removed with peritoneal dialysis, although with hemodialysis A77 1726 is cleared somewhat more rapidly and with a shorter half-life. These findings suggest that dialysis is not an effective washout procedure.

Leflunomide is contraindicated in patients with impaired liver function, severe renal impairment, severe hypoproteinemia due to causes other than RA (e.g., nephrotic syndrome, serious infections, known immunodeficiency, bone marrow dysfunction, anemia, leukopenia, neutropenia, thrombocytopenia), or known hypersensitivity to the drug. Leflunomide should be used with caution in combination with methotrexate. It is contraindicated in serious infection, and patients should be advised to seek medical advice if they note worsening fatigue, bruising, sore throat, increased susceptibility to infection, or skin or mucous membrane lesions.

Leflunomide is teratogenic in animals and therefore should be used with caution in women of childbearing age. It should not be used in women who are, or may become, pregnant or those who are breastfeeding. In women contemplating pregnancy the plasma A77 1726 level should be checked to ensure that it is below 0.02 mg/L, which the manufacturer deems to present minimal teratogenic risk. Accelerated removal using cholestyramine (8 g three times daily for 11 days) or activated charcoal should be carried out, which shortens the clearance time to 3 months. After the washout, plasma levels of the active metabolite must be evaluated and must be less than 0.02 mg/L. This plasma level must be verified by a second test performed at least 14 days after the first plasma level of less than 0.02 mg/L is achieved. Women should be advised to be sure they are not pregnant before starting leflunomide therapy and to use reliable contraception while receiving the drug. Although no data exist, it is suggested by the manufacturer that men wishing to father a child discontinue leflunomide use and undergo an accelerated removal procedure.

Immunosuppressives: cyclosporine, cyclophosphamide, azathioprine, mycophenolate mofetil

■ SARAH S. THOMAS ■ PHILIP J. CLEMENTS ■ DANIEL E. FURST

- There is some evidence that cyclophosphamide (CYC) and cyclosporine (CsA) inhibit bony damage resulting from rheumatoid arthritis.
- CYC and CsA are associated with the most serious toxicity of the disease-modifying antirheumatic drugs.
- Mycophenolate mofetil and CYC are the drugs of choice for lupus nephritis.
- Cyclophosphamide is often used in various vasculitides.

INTRODUCTION

This chapter reviews the use of disease-modifying antirheumatic drugs (DMARDs) that are not covered in other chapters, namely, azathioprine, cyclophosphamide, cyclosporine, and mycophenolate mofetil.

Because the mechanisms of action of these drugs demonstrate some similarities (as well as differences), their mechanisms of action are addressed together (Table 58.1). Likewise, the pertinent pharmacokinetics of these medications is discussed in a single section. Thereafter, the evidence for the efficacy of these drugs and their toxicities as well as tips on their use are addressed for each drug each separately.

MECHANISMS OF ACTION

Azathioprine

Azathioprine (AZA) interferes with adenine and guanine ribonucleotide via suppression of inosinic acid synthesis. Its main active metabolite is 6-thioguanine. This, in turn, is a metabolic product of AZA's principal metabolic product, 6-mercaptopurine (6-MP).^{1,2} In rheumatoid arthritis (RA), AZA reduces the numbers of circulating B and T lymphocytes (particularly suppressor, or CD8+, cells), mixed lymphocyte reactivity, immunoglobulin M (IgM) and IgG synthesis, and interleukin-2 (IL-2) secretion.

Cyclophosphamide

Active metabolites of cyclophosphamide (CYC), principally phosphoramide mustard, cross-link DNA so that it cannot replicate. CYC is cytotoxic to both resting and dividing lymphocytes.^{1,3} In RA patients CYC (intravenous [IV] or oral) suppresses helper T cell (Th) functions, decreases the number of activated T cells by 30% to 40% (which correlates with clinical improvement), and dramatically decreases the number of B cells for months.⁴

CYC suppresses primary cellular and humoral immune responses, especially if administered immediately after an antigen challenge, but it can also inhibit an established humoral or immune response. It effectively suppresses many cell-mediated immune responses such as the reaction to the delayed hypersensitivity skin test and graft-versus-host reactivity, and it is antiinflammatory.³

Cyclosporine

Cyclosporine (CsA) complexes with cyclophilin (a cytoplasmic protein), which then binds calcineurin, an intracellular phosphatase. This in turn

regulates gene transcription coding for IL-2 and other cytokines.^{3,5} Further recent data demonstrate that CsA inhibits IL-17 production by Th17 cells.⁶ Additionally, CsA is antiangiogenic in rheumatoid synovial fibroblasts via inhibition of AP-1-mediated vascular endothelial growth factor expression,⁶ which demonstrates a possible mechanism to reduce synovial proliferation.

CsA blocks the amplification of cellular immune responses and the generation of T-cell effectors and other functions dependent on IL-2. It inhibits the B-cell production of antibody to T-cell-dependent antigens, interferon- γ production, and natural killer cell activity. Growth of bone marrow-derived myeloid, erythroid, or B-lymphocyte cell line responses to T-cell-independent antigens are not affected. CsA does not impair macrophage responses to lymphokines.³

Mycophenolate mofetil

Mycophenolate mofetil (MMF) breaks down rapidly to mycophenolic acid (MPA), the active form of this drug. MPA inhibits inosine monophosphate dehydrogenase. Cyclin-dependent kinase activity is inhibited and cyclin-dependent kinase inhibitor P27 elimination is blocked. This inhibits T-cell lymphocyte proliferation and downstream effects, such as intercellular adhesion to endothelial cells. *In vitro*, the expression of E-selectin, P-selectin, and intercellular adhesion molecule 1 on endothelial cells is markedly reduced. The complementary T-cell ligands leukocyte function antigen, very late antigen 4, and P-selection glycoprotein ligand 1 are functionally impaired, which reduces T-cell adhesion to and penetration through the endothelium and reduces lymphocyte recruitment to sites of inflammation.⁷

Enteric-coated MMF sodium (EC-MPA) was designed as an alternative to MMF. EC-MPA releases a different formulation of MPA. MPA dissolves slowly after reaching the small intestine, which delays the release of MPA. EC-MPA 720 mg twice daily is therapeutically equivalent to MMF 1000 mg twice daily in renal transplant patients and apparently decreases the adverse effects relative to the non-EC compound.

PHARMACOKINETICS

Table 58.2 summarizes the most pertinent pharmacokinetic properties of these drugs. Additional comments regarding the pharmacokinetics of each drug are outlined in the following sections.

Azathioprine

AZA is chemically cleaved to 6-MP, which is catalyzed to the inactive metabolite, 6-methylmercaptopurine (6-MMP), or is methylated to the active metabolites, 6-thioguanine nucleotides (6-TGNs) and 6-methylmercaptopurine ribonucleotides (6-MMPRs). The methylation of 6-MP to active 6-TGNs and 6-MMPRs is catalyzed by thiopurine methyltransferase (TPMT), an enzyme that exhibits a threefold difference in 6-TGN alleles and helps explain the large interindividual variations seen in efficacy and toxicity when AZA is used.⁸⁻¹⁰

Eighty-nine percent of white subjects have normal to high levels of TPMT activity, 11% have intermediate activity, and 0.3% have low or absent TPMT activity.^{9,11,12} Patients with intermediate levels of TPMT activity had a relative risk of 3.1 for development of severe adverse effects (predominantly gastrointestinal) in response to AZA compared with patients with high levels of TPMT activity in one study.¹² Another study documented only

an association between low or absent TPMT and neutropenia in patients receiving AZA.¹³ Despite some inherent problems regarding measurement of erythrocyte TPMT levels, this method is a useful guide to prevent neutropenia.¹²

Among patients with chronic inflammatory disease, those with TPMT activity below 11.9 nmol/mL red blood cells $\times$ h experienced more adverse effects (rash, cholestasis, and bone marrow toxicity).¹⁴ Because secondary intracellular metabolites are the source of AZA activity, measuring plasma levels of the parent compound is not useful.

Most pertinent pharmacokinetics are outlined in Table 58.2, but the pharmacokinetics of AZA in breast milk bears mentioning. Peak breast milk concentrations of AZA are about 10% of blood levels¹⁵ with small total amounts of AZA actually being absorbed (0.008 mg/kg of infant weight per 24 hours).¹⁶ Thus, despite the very low amount of AZA getting across in breast milk, one should proceed with great caution. This is because infants might rarely be TPMT deficient, which puts them at risk of aplasia.

An approximate doubling of the 6-TGN level 1 to 3 weeks after initiation of AZA in combination with infliximab for treatment of Crohn disease has been observed, but its clinical significance is unclear.¹⁷ The therapeutic level of AZA or 6-thioguanine (6-TGN) was assumed to be the same as that in inflammatory bowel disease, but this was shown inappropriate, at least for systemic lupus erythematosus, in which response was seen at “subtherapeutic” 6-TGN levels.¹⁸ On the other hand, high levels of 6-TGN correlated with a combination of abnormal results on liver function tests and neutropenia, so metabolite levels may help guide drug dosing.¹²

Cyclophosphamide

CYC itself is not cytotoxic, but it is enzymatically converted by hepatic microsomal (cytochrome P450) enzymes to multiple metabolites, of which phosphoramidate mustard is probably the most active urinary cytotoxic agent.^{1,19} CYC and its metabolites are excreted largely by the kidney. The drug is extensively metabolized before excretion, with less than 25% of the administered dose appearing in the urine unchanged. Of the urinary metabolites, carboxyphosphamide accounts for about 50% and 4-ketophosphamide

for about 15%.¹⁹ The concurrent use of sodium-2-mercaptoethane sulfonate (mesna) may detoxify acrolein (also a urinary metabolite), CYC's bladder-toxic metabolite, and thus reduce bladder toxicity.²⁰ Only small amounts of radioactively labeled drug or metabolite appear outside the urinary tract.^{1,21}

Because dialysis removes 72% of CYC, the drug should be administered after dialysis, and the dose should be reduced when CYC is administered to patients with renal failure. Allopurinol and cimetidine (but not ranitidine) inhibit hepatic microsomal enzymes, which results in increased CYC alkylating metabolite levels.¹⁹

Glomerulonephritis, including decreased serum albumin and increased urinary protein levels, as well as CYP2B6*9 and ABCB1 C3435T polymorphisms, increased CYC concentrations; the area under the curve increased ($r = -0.392$) and plasma CYC clearance decreased ($r = -0.392$). Special care should be exercised when using CYC in the presence of increasing glomerulonephritis.²²

Cyclosporine

Absorption of the usual CsA formulation is erratic and incomplete.^{23,24} The CsA microemulsion formulation is associated with a significant increase in the rate, extent, and consistency of absorption.²⁵ On a milligram-for-milligram basis, this has resulted in a 20% to 30% increase in exposure to CsA.²⁵ Preprandial treatment with the microemulsion further improves its efficacy in nephritic syndrome, improving outcome in 63% to 84% of patients.²⁶ CsA is a strong substrate for CYP3A4, so drugs that induce CYP3A4 (e.g., rifampin, phenobarbital, phenytoin) decrease its level, whereas drugs that inhibit CYP3A4 (ketoconazole, diltiazem) increase its level (Table 58.3). Grapefruit juice also increases drug level (by 62% in one study) because of its inhibition of CYP3A4 activity.²⁷ CsA is largely distributed outside the blood volume. It is highly bound to plasma proteins, erythrocytes, and lipoproteins.^{23,24} About 11% of a CsA dose is found in infant cord blood.²⁸ CsA is metabolized in the liver by the cytochrome P450

TABLE 58.1
Mechanisms of action

Drug	Active agent(s)	Mechanism
Azathioprine	6-thioguanilic acid, 6-methylmercaptopurine ribonucleosides	Interferes with adenine and guanine ribonucleotides
Cyclophosphamide	Phosphoramidate mustard (metabolite)	Cross-links DNA
Cyclosporine and other IL-2 inhibitors	Parent compound and up to 15 metabolites	Suppresses IL-2 synthesis and release Suppresses T-cell response and interaction
Mycophenolate mofetil	Mycophenolic acid	Interferes with inosine monophosphate Dehydrogenase inhibits T-cell and endothelial function

IL-2, interleukin-2.

TABLE 58.3
Drug interactions with cyclosporine

Drugs that increase IL-2 inhibitor concentrations (inhibit CYP3A4)	Drugs that decrease IL-2 inhibitor concentrations (induce CYP3A4)
Antacids: metoclopramide, cisapride	Anticonvulsants: phenytoin, carbamazepine, phenobarbital
Antifungals (azoles): ketoconazole, itraconazole	Antituberculosis drugs: rifampin
Antituberculosis drug: isoniazid	Antibiotics: nafcillin, aminoglutethimide
Calcium channel blockers: diltiazem (cyclosporine, rapamycin only), nifedipine, verapamil	Miscellaneous: St. John's wort
Antibiotics: ciprofloxacin, clarithromycin, erythromycin, doxycycline, protease inhibitors	
Miscellaneous: grapefruit juice, quinidine, diclofenac	

CYP3A4, cytochrome P450 isoenzyme 3A4; IL-2, interleukin-2.

GI, gastrointestinal; 6-MP, 6-methylmercaptopurine.

mixed function oxidase to at least 15 known metabolites, some of which have immunosuppressive properties.^{23,24} CYP3A (hepatic metabolizing enzyme) activity correlates with CsA dosing requirement after renal transplant ($r = 0.55$).²⁹ At steady state, colonic tissue CsA concentrations are 50 to 250 times blood levels, which indicates significant tissue concentration of CsA. Elimination of CsA is primarily via the biliary system, with only small amounts appearing in the urine.^{23,24}

Administration of CsA with other nephrotoxic agents such as amino glycosides and nonsteroidal antiinflammatory drugs may increase its nephrotoxic potential.^{23,24} CsA may potentiate the action of methotrexate (MTX) by inhibiting metabolism of MTX to its less active forms.³⁰

Mycophenolate mofetil

MMF is rapidly changed to MPA, the active moiety. MPA is 93% bioavailable with a clearance of 11 L/hr and an elimination half-life of 11 to 16 hours.³¹ Although 90% is renally excreted, there is an enterohepatic recirculation that can supply a safety valve if renal insufficiency supervenes.³¹

The concentration of MPA correlates with serum bilirubin, creatinine, and albumin concentrations and thus is affected by both renal and liver disease.³¹ MPA pharmacokinetics was positively correlated with therapeutic responses of MMF in patients with biopsy-proven World Health Organization (WHO) class III or IV lupus nephritis.³² Monitoring the activity of inosine monophosphate dehydrogenase as a biomarker of MPA-induced immunosuppression is being considered as a novel approach in pharmacokinetics/pharmacodynamics-guided therapy.³³

Besides the degree of renal and hepatic disease (mentioned earlier), other factors such as bowel decontamination and enterohepatic recirculation affect MPA concentrations (contributing to a mean of 29% of MPA bioavailability).³⁴ CsA increases MPA concentrations, possibly by augmenting the bioavailability of MMF by inhibiting MPA glucuronidation.³⁴ Tacrolimus augments the bioavailability of MMF through inhibition of MPA glucuronidation.³⁵ Three clinical trials showed that patients concurrently receiving a proton pump inhibitor had MPA plasma concentrations that were significantly lower by approximately 43% at 2 g of MMF daily (but not at 3.0 g daily), possibly due to decreased absorption. At lower dosages, this increases the risk of treatment failure.³⁶⁻³⁸

Although these interactions speak to the need for monitoring MPA concentrations in transplant patients, monitoring of MPA levels in rheumatology is not common practice.

EFFICACY, TOXICITY, AND THERAPEUTIC USE

Azathioprine

Efficacy

AZA 1.25 to 3.0 mg/kg/day is more effective than placebo in treatment of RA^{1,2} (Table 58.4). There appears to be a dose-response relationship in RA, based on a comparison of placebo with AZA 1.0 mg/kg/day and AZA 2.5 mg/kg/day (although the data are not completely consistent).² A meta-analysis of three trials that included 81 RA patients who were treated with AZA reported that AZA was more effective than placebo (odds ratio, 1.45 to 10.50), as expected. Adverse reactions were also statistically more frequent in the AZA group.³⁹

In controlled trials comparing AZA with other DMARDs (CYC, CsA, chloroquine), results are inconsistent. However, AZA was not as effective as MTX in the treatment of RA.⁴⁰

A small placebo-controlled trial involving eight patients with reactive arthritis in a crossover design showed positive results over 4 to 6 months.⁴¹ A 16-patient controlled trial comparing AZA plus prednisone to prednisone

alone in polymyositis/dermatomyositis showed the superiority of AZA only after 3 years of follow-up; at 3 months no differences between the two regimens were discernible.² A placebo-controlled 2-year study of 73 patients with Behçet syndrome (37 of whom received AZA) concluded that AZA effectively controlled the progression of Behçet syndrome, especially the associated eye disease.⁴² A meta-analysis of studies using AZA for the treatment of renal systemic lupus erythematosus (SLE) reported that AZA plus steroids decreased renal SLE all-cause mortality (relative risk, 0.60; 95% confidence interval, 0.36 to 0.99) but did not alter renal outcomes; this combination treatment was not associated with increased infections compared with steroids alone.⁴³ An open 2-year study in 75 SLE patients demonstrated that AZA was equivalent to CsA in preventing lupus nephritis flares.⁴⁴ One study supported the use of AZA in scleroderma-associated lung disease.⁴⁵

In a prospective, open-label, multicenter, randomized trial, AZA (2.0 mg/kg/day) and MTX (25 mg/wk) for 12 months were shown to be equally effective alternatives for maintenance therapy in patients with granulomatosis with polyangiitis (previously known as *Wegener granulomatosis*) and microscopic polyangiitis. Among 159 eligible patients, 79% experienced remission after receiving corticosteroids and CYC as induction therapy. They were randomly assigned to receive either AZA or MTX ($n = 63$ per group). Those patients were followed for a mean of 29 months. Twenty-three patients who received AZA (37%) and 21 patients who received MTX (33%) experienced a relapse ($P = .71$); most (73%) experienced a relapse only after discontinuation of the study drug.⁴⁶

Toxicity

The most common adverse event seen with AZA is gastrointestinal intolerance, including nausea and diarrhea. Other toxic effects include rash, pancreatitis, cholestatic hepatitis, stomatitis, and perhaps viral infections¹ (Table 58.5). A 50-fold increase in relative risk of malignant disease (particularly non-Hodgkin lymphoma) was seen in AZA-treated renal transplant patients.² In RA, the AZA-related risk of lymphoma (and non-Hodgkin lymphoma) is confounded by an increased relative risk associated with RA itself.² Overall, there is probably a small added risk of developing some malignancy when using AZA in RA of 1.3 and a relative risk of between 2.2 and 8.7 for developing a lymphoproliferative disorder.^{1,2} Reversible lymphoma associated with Epstein-Barr virus infection has also been observed after AZA therapy.⁴⁷ Bone marrow toxicity has been associated with intermediate or reduced (especially low or absent) levels of TPMT in RA patients (see the section on AZA pharmacokinetics earlier).^{9,11,12,48}

Therapeutic use

Before AZA is used, a discussion of risks and treatment goals should be conducted and a good history taking, physical examination, and laboratory testing should be performed. Measurement of TPMT activity is useful to determine the likelihood of bone marrow toxicity.⁴⁸ However, TPMT levels are higher in new red blood cells, so the levels should not be determined shortly after bone marrow depression or during the posttransplant response of increased erythropoiesis.

An alternative to testing TPMT levels for predicting AZA sensitivity is to institute a daily dose of 25 to 50 mg for the first week followed by determination of a complete blood count. Thereafter, doses are increased regularly by 0.5 mg/kg/day every month, with a goal of 2 to 3 mg/kg/day. The dose may then be adjusted to the minimum effective dose.

Monitoring includes determination of hemoglobin level, white blood cell count, and platelet counts every 2 weeks while dosing regimens are being changed and every 4 to 12 weeks during stable regimens. Liver function tests can be performed every 6 to 12 weeks, after initial testing at 2 to 4 weeks. Monitoring for lymphoproliferative disease and other malignancy is appropriate but undefined, as is monitoring for pregnancy.

Cyclophosphamide

Efficacy

In five placebo-controlled trials in RA, oral CYC was consistently better than placebo when used in dosages of more than 1.5 mg/kg/day, both clinically and in terms of erythrocyte sedimentation rate (ESR) and rheumatoid factor levels.²⁰ It has not been consistently effective in dosages less than 1.0 mg/kg/day. CYC reached its peak effectiveness after approximately 16 weeks. In small studies, CYC retarded bone destruction.²⁰

Compared with other DMARDs, CYC is equal to AZA and is equal or superior to intramuscular gold with regard to both clinical and radiologic endpoints.²⁰ Due to toxicity issues and the availability of better newer agents, CYC is principally used now only to treat the extraarticular manifestations of RA (e.g., vasculitis or interstitial lung disease).

AZA, azathioprine; CsA, cyclosporine; CYC, cyclophosphamide; GFR, glomerular filtration rate; MMF, mycophenolate mofetil; ±, additional studies and meta-analyses are needed to provide conclusive evidence.

Until recently, the treatment of choice for lupus nephritis (particularly [WHO] class III focal proliferative nephritis and class IV diffuse proliferative nephritis) was CYC. CYC was administered as 14 IV infusions of 0.5 to 0.75 g/m² over 30 months.^{43,49,50} In that protocol, the induction phase included the first six monthly CYC infusions, followed by a maintenance phase that included eight quarterly CYC infusions. Since publication of the results of randomized trials comparing MMF and CYC, the place of CYC as the drug of choice for SLE nephritis has been questioned.⁵⁰

High-dose IV CYC (50 mg/kg for 4 days, 200 mg/kg total dose) was compared with IV CYC 750 mg/mo for 12 months in a randomized clinical trial in patients with renal and central nervous system SLE.⁵¹ For the first 12 months the high-dose CYC group fared significantly better than the group receiving the monthly lower-dose CYC, although these differences disappeared by 30 months⁵¹ (Table 58.6).

A 10-year follow-up of the Euro-Lupus Nephritis Trial (ELNT) comparing low-dose IV CYC with high-dose IV CYC showed no significant differences between treatment groups in rates of all-cause death (5 of 44 patients [11%] in the low-dose group vs. 2 of 46 patients [4%] in the high-dose group), sustained doubling of serum creatinine level (6 of 44 [14%] vs. 5 of 46 [11%], respectively), and end-stage renal disease (2 of 44 [5%] vs. 4 of 46 [9%], respectively); similarly, there were no differences between groups in mean serum creatinine level, 24-hour proteinuria, and damage score at 10 years follow-up. This study confirms that a low-dose IV CYC regimen followed by AZA—the Euro-Lupus regimen—achieves good clinical results in the very long term.⁵⁰

A registry study examined the effect of CYC on pulmonary catastrophic antiphospholipid syndrome (p-CAPS) compared with SLE-CAPS.⁵² CYC treatment was associated with increased mortality in p-CAPS, whereas CYC improved survival in SLE-CAPS. Selection bias may have skewed the results, so these findings must be viewed very cautiously.

The treatment of the systemic vasculitides (antineutrophil cytoplasmic antibody [ANCA]-associated granulomatous vasculitis, microscopic polyarteritis, and crescentic glomerulonephritis) has been divided into the phases of remission induction and maintenance therapy. The induction phase has usually included CYC, AZA, or MTX.⁵³⁻⁵⁶ The rate of relapse was lower and the event-free survival was greater ($P < .05$) in patients receiving 12 monthly pulses of IV CYC than in those receiving 6 monthly pulses.⁵⁴ A 12-month open randomized trial comparing CYC and MTX showed the noninferiority of MTX to CYC for controlling ANCA+ vasculitis.⁵⁶ Unfortunately, the time to remission was longer in the MTX group, and the relapse rate after stopping MTX was higher than that of the CYC group.

Remission induced by CYC could be successfully maintained by therapy with AZA or MTX over 18 months, but relapse rate by 18 months was significantly higher when MTX was used for maintenance⁵⁴ than when CYC was continued. Another study comparing MTX with AZA for maintenance after induction with IV CYC showed that adverse events and efficacy were no different for the two therapies.⁴⁶

IV CYC (up to 900 mg/m²) without maintenance has real but limited usefulness in ANCA-associated granulomatous vasculitis, because 52% of patients experience relapse despite good initial response.⁵⁷ Comparison of daily oral CYC (2 mg/kg/day) with pulse CYC (15 mg/kg orally or intravenously every 2 to 3 weeks) in patients with ANCA-associated vasculitis who were taking prednisolone showed that the pulse CYC induced remission at a lower cumulative CYC dose and caused less leukopenia.⁵⁷ CYC added nothing to corticosteroids alone in the treatment of biopsy-proven Henoch-Schönlein purpura in an open-label trial involving 54 adults.⁵⁸ An eight-patient open trial of fortnightly administration of CYC (15 mg/kg IV) for treatment of pemphigus vulgaris indicated efficacy in all patients.⁵⁹

A 1-year placebo-controlled trial of oral CYC for systemic sclerosis (SSc)-associated interstitial lung disease showed a modest effect on forced vital capacity and more robust effects on dyspnea, ability to perform activities of daily living, quality of life, and skin thickening.⁶⁰ A double-blind, randomized, placebo-controlled trial in a group of 45 patients with SSc interstitial lung disease given 6 monthly IV CYC treatments, followed by 6 months of oral AZA, generally supported these results.⁴⁵ Open-label studies also supported the efficacy of CYC in SSc interstitial lung disease. The beneficial effects eventually faded after CYC was stopped.^{61,62} This suggests that immunosuppressive therapy may be needed for longer than 1 year (approximately 2 to 3 years) to prevent relapse.

Toxicity

CYC's significant toxicity is the major factor limiting its clinical use in the rheumatic diseases. A major toxicity is carcinogenicity (especially bladder cancer). Kinlen's experience with 643 RA patients suggests a relative risk of 1.8 for all cancers combined, a relative risk of 13.0 for non-Hodgkin lymphoma, and a relative risk of 12.8 for bladder cancer.⁶³ On the other hand, in a placebo-controlled trial of oral CYC for the treatment of SSc interstitial lung disease, most toxicities (including gastrointestinal) were equal to those with placebo over 1 year of treatment, and only the frequency of leukopenia was increased ($P < .0001$). After an additional 1 year in which patients were observed but were not treated with any study medication, there were no differences in the rates of cancer, serious adverse events, or deaths in the CYC group compared with the placebo group.⁶⁴

Irreversible azoospermia was regularly produced in adult males receiving a total dose of more than 18 g of CYC, although plasma testosterone levels remained normal. The risk of infertility and amenorrhea in women receiving CYC rises with increasing duration of therapy, dose, and age. In postpubertal females, both gametogenesis and hormonal function are altered adversely, and menopause occurs.

A study of 17 women demonstrated amenorrhea in all the patients receiving cyclophosphamide. In those given a luteinizing hormone-releasing agent, menstruation returned and ovarian dysfunction reversed when CYC was stopped. In those not given the agonist, ovarian function did not return.⁶⁵ Somers and coworkers also reported that ovarian function could be protected by a depot leuprolide acetate injection in SLE patients given CYC.⁶⁶

In a randomized clinical trial, women with granulomatosis with polyangiitis who had been exposed to CYC before study enrollment were found to have diminished ovarian reserve at entry and a higher rate of early menstruation cessation while being treated in the study. Among women with normal

Serum Cr, albumin, C3, 24-hr urinary protein, and DAS significantly improved in both groups during first year of F/U ($P = .005$). Renal flares in 27% of low-dose group vs. 29% of high-dose group ($P = .8$).	Episodes of severe infection twice as frequent in high-dose group ($P = .2$).
Mitwalli, et al. ¹⁰⁹	DB, RCT	42	LN WHO class IV	Group II: Low-dose IV CYC followed by AZA* on a background of oral prednisolone†	Group I: CYC + prednisolone, HCQ, and AZA† Group II: CYC + prednisolone, HCQ, and AZA†	73 44	Patients followed for 10 yr. Kidney survival over time equal in both groups ($P = .288$). ESRD: group I (13.9%) > group II (29.4%) ($P = .36$).	Gonadal toxicity and malignancy: group I > group II ($P = .0000$). Infections: group I (31.3%) > group II (31.6%) ($P = .019$). Amenorrhea: group I > group II ($P = .006$).
Petri, et al. ¹¹⁰	RCT	30	Renal lupus, neurologic lupus, or other organ system involvement with moderate to severe activity	Group I: IV CYC	750 mg/m ² BSA monthly × 6 mo then quarterly × 2 yr 50 mg/kg daily × 4 days	26 21	At 6-mo F/U, complete response [§] achieved in 52% of group II vs. 35% of group I ($P = .13$). At 30-mo F/U, complete response in 48% of group II vs. 65% of group II ($P = .13$).	Serious infections: 15 in group I vs. 11 in group II. Premature ovarian failure: 30% of group II vs. 43% of group I at 12 mo.
Austin, et al. ¹¹¹	RCT	12	LMN	Group I: CsA Group II: IV CYC Group III: prednisone	5 mg/kg body wt/day × 11 mo 0.5 to 1.0 g/m ² BSA every other mo × 6 cycles 1 mg/kg body wt every other day × 6 wk	12 15 15	At 1 yr, cumulative probability of remission of proteinuria was 27% with prednisolone, 60% with IV CYC, and 83% with CsA. Relapse of nephrotic syndrome occurred significantly more often after completion of CsA than after IV CYC ($P = .02$).	Infections: pneumonia (6.7% with prednisone and 16% with CsA), localized herpes zoster (13% with IV CYC), others.

*AZA (2 mg/kg/day) started in both groups 2 wk after the last injection of CYC and continued 30 mo after inclusion in study.

†All patients received 3 daily pulses of 750 mg of intravenous methylprednisolone, followed by oral glucocorticoid therapy (5–7.5 mg prednisolone/day). This dosage was maintained at least until month 30 after inclusion in study.

‡Maintenance therapy included the following: prednisolone 1 mg/kg/day started in both groups for 4 wk, tapered to 0.2 mg/kg an alternate days for 24 mo; HCQ 200 mg/day, AZA 1 mg/kg body weight/day for 24 mo.

§The major outcome measure was response as determined by the Responder Index for Lupus Erythematosus. This measure defined complete response, partial response, no change, or worsening for each organ manifestation.

||Complete remission was defined as proteinuria of <0.3 g protein/day. Partial remission was defined as proteinuria of <0.2 g protein/day with >50% reduction from baseline proteinuria.

¶Other infections were sinusitis, bronchitis, otitis media, dental abscess, upper respiratory tract infection, syphilis, pelvic inflammatory disease, cholecystitis, and herpes simplex virus skin infection.

baseline ovarian function, six of eight who received CYC during the trial developed diminished ovarian reserve, compared with none of four who did not receive CYC ($P < .05$). Daily oral CYC, even when administered for fewer than 6 months, causes diminished ovarian reserve.⁶⁷

The urologic adverse effects of CYC are thought to be related to its urinary metabolite acrolein (see earlier section on CYC pharmacokinetics). Hemorrhagic cystitis has been reported in about one third of lupus nephritis patients receiving oral CYC daily, and there was a significant but much lower incidence of bladder fibrosis and bladder carcinoma.⁶⁸ In a cohort study of 119 RA patients, 9 developed bladder cancer during an average 13.1 years of follow-up, although three bladder cancers occurred after 14, 16, and 17 years.⁶⁹ Cystitis and bladder carcinoma are markedly reduced when CYC is used on an intermittent IV basis. Bladder toxicity can also be reduced by the concomitant administration of mesna.⁷⁰ Because mesna is administered intravenously, it is useful primarily when CYC is given intravenously.

Therapeutic use

Because CYC has significant toxicity, its use in RA should be limited to patients with extraarticular manifestations suggestive of polyarteritis-like disease and those for whom all other DMARDs, including biologics, have failed but who still have severe active RA. In these cases, oral CYC dosages of 2 mg/kg/day might be considered. An IV regimen of CYC has been suggested for management of rheumatoid vasculitis.⁷¹ In this regimen, 500 to 1000 mg of CYC and 500 to 1000 mg of methylprednisolone was given intravenously on days 1, 8, 29, and 58. Patients were continued on oral DMARDs. In either case, once the disease is under control, switching to a less toxic drug over a longer period should be considered.

Whenever CYC is used in the management of SLE-associated diffuse proliferative glomerulonephritis, it is usually started at 0.50 to 0.75 g/m² when the glomerular filtration rate (GFR) is greater than one third of the predicted normal value. When renal function is less than one third of normal, the starting dose is 0.5 g/m². CYC can be administered in 150 mL of a 5% glucose solution over 30 to 60 minutes. There are no established regimens for giving IV mesna with IV CYC to reduce bladder toxicity. The general rule, however, has been that its dose should be equivalent to the CYC dose and that it should be given in two to three divided doses over several hours.

Diuresis should be ensured by increased IV and oral fluids and possibly diuretics. Nausea and vomiting are common and may require antiemetic therapy (prophylactically and as needed). IV pulse methylprednisolone (10 to 100 mg) or dexamethasone (10 mg) may also be given. This may help decrease nausea and is also part of the treatment for glomerulonephritis.

As an induction therapy in SLE nephritis, IV pulse CYC (with or without IV methylprednisolone) may be given once every month for 6 months. After the completion of the 6-month induction period (using either CYC or MMF) there are three well-documented approaches to maintenance therapy: (1) IV CYC given every 3 months for up to 2 more years of therapy; (2) AZA; and (3) MMF. Maintenance therapy may be required for many years.

CYC given orally has been the preferred method for managing polyarteritis and ANCA-associated granulomatous vasculitis.¹ The initial dose should be 1 mg/kg/day with a goal of reaching 2 mg/kg/day (approximately 75 to 125 mg/day) and should be altered to maintain the white blood cell count at more than 3000/mm³.

Complete blood count, platelet count or estimate, and urinalysis with microscopic examination should be performed every 7 to 14 days initially and can be reduced to every 2 to 4 weeks once the disease and dose have been stabilized for 2 to 3 months.

Avoidance of pregnancy is strongly recommended. Consideration might be given to using oral contraceptives or gonadotropin-releasing hormone inhibitors if the patient is interested in preserving fertility, although the use of these medications in this context is still exploratory.^{67,72}

Cyclosporine

Efficacy

Placebo-controlled trials, including one trial in which a medium dose of CsA was compared with a low dose, have been performed and show that CsA is efficacious in treatment of RA.⁷³⁻⁷⁵ In these studies, nearly 400 subjects with RA received CsA in initial dosages of 1 to 10 mg/kg/day. CsA improved clinical symptoms and signs; however, no significant improvement was noted in laboratory parameters such as ESR or rheumatoid factor titers. On the basis of these studies and a meta-analysis,⁷⁴ patients treated with 2.5 to 4.0 mg/kg/day of CsA should show a substantial response within the first month. CsA and MTX was better than MTX or placebo in patients showing an incomplete response to MTX.⁷⁵ In a trial of sequential induction and maintenance treatment in patients with proliferative lupus nephritis and

preserved renal function CsA was as effective as CYC. Regimens containing CsA or IV CYC are each more effective than prednisone alone in inducing remission of proteinuria in patients with lupus nephropathy.⁷⁶

In children with steroid-resistant nephrotic syndrome, a high remission rate was achieved using a combined CsA/prednisolone treatment regimen in a 12-month prospective, multicenter trial involving 35 children. Major adverse events were severe bacterial infections (two patients) and posterior reversible encephalopathy syndrome (one patient).⁷⁷

A pediatric open, randomized, controlled trial in patients with Henoch-Schönlein nephritis pitted CsA (5 mg/kg/day) against methylprednisolone (3- to 30-mg/kg pulses followed by oral prednisone) over 12 months. In all 11 patients receiving CsA nephrotic-range proteinuria resolved by 3 months, whereas 6 of 13 methylprednisolone-treated patients failed to show a response. Biopsy-assessed response was similar over 2 years, and follow-ups to 6 years continued to show an advantage for CsA.⁷⁸ Two blinded trials found that CsA was superior to conventional therapy (colchicine or prednisone/chlorambucil) in the management of Behçet syndrome, particularly its ocular complications.^{5,79} CsA has been successfully used in open trials and anecdotal series for treatment of dermatomyositis,⁸⁰ ANCA-associated granulomatous vasculitis, and systemic sclerosis.⁸¹ In psoriasis, CsA appeared to be as effective as MMF.⁸² CsA seems to be effective in clearing cutaneous lesions in psoriasis⁵ and is a possible choice for treatment of psoriatic arthritis.⁸³

CsA was superior to MMF in treatment of skin and nail psoriasis in a multicenter, randomized, open-label trial of MMF (2 g/day; $n = 27$) versus CsA (2.5 mg/kg/day; $n = 27$) for 12 weeks; CsA improved the skin more than MMF ($P = .02$).⁸⁴ In a 12-week randomized controlled trial, CsA (5 mg/kg/day) significantly improved plaque psoriasis more than did MTX (15 mg/wk) and was equivalent with regard to patient quality of life and adverse events.⁸⁵ In a 24-week double-blind, randomized, controlled trial of a microemulsion formulation of CsA, patients with plaque psoriasis who had achieved remission while taking standard CsA were given the CsA microemulsion at 5 mg/kg/day for 2 days a week or placebo.⁸⁶ Results showed that CsA prevented clinical worsening in 69.9% of patients with baseline moderate or severe psoriasis versus 46.3% for placebo ($P = .01$). However, the results lost significance if patients with mild psoriasis were included ($P = .07$).⁸⁶

Toxicity

When CsA is used to treat rheumatic disease, adverse effects are generally mild and reversible at low doses.^{5,24} Dose-related decreases in GFR often occur with corresponding increases in serum creatinine level (the principal adverse effect). Over 12 months, a more than 30% increase in creatinine concentration was noted in 48% of the RA patients studied.⁸⁷ In patients taking more than 5 mg/kg/day, CsA renal biopsy specimens sometimes showed focal interstitial fibrosis, tubular atrophy, and/or arteriolar lesions. However, these did not occur if the dosage of CsA remained 5 mg/kg/day or less and if serum creatinine level did not rise more than 50% above baseline.⁸⁸ New-onset hypertension has been reported in about one third of rheumatoid and psoriatic arthritis patients treated with CsA. Although antihypertensive therapy may be required, potassium-sparing diuretics should be avoided because CsA may cause hyperkalemia. Because diltiazem (but not isradipine or nifedipine) may increase CsA levels by decreasing its metabolism, changes in CsA dosage may be required in patients using diltiazem.

Significant hepatotoxicity manifested as elevated levels of hepatic enzymes and bilirubin may be seen but usually only with higher CsA doses.⁸⁹ In psoriatic arthritis patients treated for up to 24 months, hypertrichosis occurred in 24%, neurologic disturbances in 7%, gum hyperplasia in 12%, and gastrointestinal complaints (mostly nausea) in 9% of patients.⁹⁰ Lymphomas have been observed with this drug, including reversible Epstein-Barr virus-associated lymphomas. In a secondary analysis of registry data, CsA was found to be associated with osteoporosis, although well-controlled trials will be necessary to confirm these data.⁸⁹ In a large randomized study, an increase in insulin-like growth factor (somatomedin C) levels and insulin-requiring diabetes was seen in RA patients⁹¹ during long-term CsA therapy. This, too, will need further study.

Therapeutic use

Consensus guidelines for the use of CsA in RA (for both conventional and microemulsion formulations) have been published and should be reviewed by any practitioner using CsA.⁸⁸ CsA should be avoided in patients with preexisting renal disease (creatinine clearance of less than 60 mL/min).

Both conventional and microemulsion formulations may be instituted at 2.5 mg/kg/day in two divided doses every 12 hours. The dosage may be cautiously increased by 0.5 to 0.75/kg/day every 4 to 8 weeks until a

maximum dosage of 5 mg/kg/day for the conventional formulation (or 4 mg/kg/day for the microemulsion) is reached, unless this is prevented by a rise in serum creatinine concentration of 30% or greater. Dosage reductions of 0.5 to 0.75 mg/kg/day are warranted if serum creatinine level increases above baseline by 30% or if uncontrolled hypertension appears (systolic pressure of more than 140 mm Hg and/or diastolic pressure of more than 90 mm Hg). Hypertension can usually be managed with calcium channel blockers (especially isradipine or nifedipine) and β -blockers.

Drug interaction

MPA delays CsA absorption, which indicates a potentially important drug-drug interaction. Thus the institution of CsA therapy may require adjustment of MPA dose when MPA and CsA are to be used together.

Mycophenolate mofetil

Efficacy

In one study (available in abstract only) there was no difference between 2 g and 4 g MMF daily for the treatment of RA.⁹² The response rate according to American College of Rheumatology 20% improvement criteria was 29% for 2 and 4 g MMF daily and 47% for 5 g daily.

A double-blind, randomized, controlled trial involving 227 patients with SLE renal disease showed that MMF (2 g/day) was superior to AZA (2 mg/kg/day) in "time to treatment failure" (defined as death, end-stage renal disease, doubling of serum creatinine level, need for rescue therapy, or renal flare).⁵⁰ Serious adverse events occurred in 33.3% of AZA-treated patients versus 23.5% of MMF-treated patients ($P = .02$).

Three meta-analyses were performed, each of which included data for several hundred patients with high-grade SLE nephritis. All meta-analyses showed a statistically significant ($P < .05$) advantage in remission rates for MMF with a relative risk of 1.5 to 3.0. All meta-analyses reported statistically significant lower rates of infectious complications with MMF (relative risk, 0.65 to 0.5) and a strong trend for less amenorrhea. On the other hand, there was a strong trend for increased rates of gastrointestinal adverse effects with MMF.⁹³

Double-blind studies using MMF in the treatment of lupus proliferative and membranous glomerulonephritis have shown this drug to be effective in these patients.^{50,94-96} In a meta-analysis encompassing 10 randomized controlled trials and 847 patients with SLE proliferative nephritis, renal remission rates were the same for CYC and MMF (relative risk, 1.052; 95% confidence interval, 0.950 to 1.166), as were the risks of death and end-stage

renal disease.⁹⁶ A meta-analysis of five studies stated that MMF is preferred over CYC in treatment of SLE nephritis.⁹⁷

Uncontrolled studies of children with lupus ($N = 52$) and some with renal lupus ($N = 31$) indicated that 69% to 85% of patients showed a response to MMF.^{98,99} MMF has been used in multiple other diseases, including bullous pemphigoid,⁸⁴ microscopic polyangiitis,¹⁰⁰ SSC cutaneous thickening and interstitial lung disease,¹⁰¹ and autoimmune hepatitis.¹⁰² In a controlled trial, patients in remission from ANCA-associated vasculitis (granulomatosis with polyangiitis or microscopic polyangiitis) received either AZA (2 mg/kg/day; $n = 80$) or MMF (2.0 g/d; $n = 76$), relapses were more common in those receiving MMF (60%) than in those given AZA (37.5%) (hazard ratio, 1.69; $P = .03$). Other outcomes, including severe adverse events, did not differ in the two groups.¹⁰³

Toxicity

Comparisons with AZA in the renal transplantation literature show that AZA and MMF have similar gastrointestinal, hematopoietic, and hepatic toxicity profiles.⁵⁰ Diarrhea is the most common adverse effect observed. Nausea, leukopenia, anemia, thrombocytopenia, thinning of scalp hair, pancreatitis, and bacterial and viral infections have also been seen. In a recent meta-analysis encompassing five trials and 683 patients, infections and gastrointestinal adverse effects occurred at similar rates in patients taking MMF and in those taking CYC, but leukopenia occurred less frequently in those taking MMF.⁹⁷ MMF was a greater risk in pregnancy than CsA, causing increased first-trimester pregnancy loss and multiple congenital malformations. It was also more often associated with herpes simplex and herpes zoster than CsA.¹⁰⁴

Therapeutic use

MMF is an immunosuppressive drug, but it also has effects on nonimmune cells (e.g., vascular smooth muscle cells, fibrocytes). It has therapeutic value in SLE-associated kidney disease and may replace CYC as the drug of first choice for lupus nephritis.¹⁰⁵ Systolic and diastolic blood pressure does not seem to be increased when MMF is taken.¹⁰⁶

The drug can be instituted at a dosage of 0.5 g twice daily for 1 week. The dosage can then be increased to 1.0 g twice daily for 1 week and then to 1.5 g twice daily, if one wishes. MMF can be taken before or with food.

In renal transplant patients, a dose of 720 mg of enteric-coated MPA has been demonstrated to be therapeutically equivalent to a 1000-mg dose of MMF. Laboratory monitoring for toxicity requires testing every 1 to 3 months for hematologic and hepatic toxicity.

T-cell costimulation and other directed therapies

■ ERNEST H. CHOY

- T cells are pathogenic in rheumatoid arthritis (RA) and have an important role in sustaining synovitis even in established disease.
- Abatacept, a fusion protein of recombinant human cytotoxic T lymphocyte antigen 4 conjugated to the Fc portion of human immunoglobulin, blocks the costimulatory molecule CD28 binding to B7-1 and B7-2 and thereby modulates T-cell activation.
- Modulation of T-cell activity by blocking of costimulatory signals suppresses inflammation and improves prognosis in RA as evident from the efficacy of abatacept, which is licensed for the treatment of RA in patients who have failed to show a response to disease-modifying antirheumatic drugs or tumor necrosis factor antagonists.
- Adverse effects of abatacept include increased susceptibility to infection, infusion- or injection-site reaction, and reduced protective humoral response to vaccines.
- Recently a subcutaneous formulation of abatacept has been approved in the United States and Europe for the treatment of RA. Its efficacy and safety profile are similar to those of intravenous abatacept.

RATIONALE FOR TARGETING T CELLS IN RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a chronic immune-mediated inflammatory disease primarily affecting the articular joints. Although the cause of RA remains unknown, a considerable amount is now known about the pathologic processes involved in the disease. Because this has been addressed in detail elsewhere in this book, only a brief summary is given here. RA may be initiated by an unknown antigenic peptide derived either from an exogenous antigen (e.g., an infectious agent) or an autoantigen. The putative arthritogenic peptide is presented by the RA-associated major histocompatibility complex class II molecules, such as human leukocyte antigen (HLA)-DRB1*0404 or HLA-DRB1*0401, to arthritogenic CD4+ T cells. These CD4+ T cells become activated, release interleukin-2, and clonally expand. Their production of various other cytokines and growth factors activates other cell types, including B cells, monocytes/macrophages, and synovio-cytes, and enhances leukocyte recruitment into the joint. These processes together generate the immune-inflammatory cascade of synovitis. The beneficial effect of the anti-T-cell drugs cyclosporine A, tacrolimus, and recently the biologic agent abatacept (Orencia, Bristol-Myers Squibb, Princeton, N.J.), which inhibits T-cell activation by blocking costimulatory signals, even in patients with long-standing disease, argues strongly in favor of a continuing role for T cells.

COSTIMULATORY SIGNAL IN T-CELL ACTIVATION

The activation signal resulting when a T-cell receptor of a naive T cell binds to an antigenic peptide presented in the HLA groove of an antigen-presenting cell is known as *signal 1*.¹ However, signal 1 alone is insufficient for full T-cell activation, which is required for triggering cytokine production, clonal expansion, prevention of anergy, and resistance to apoptosis.¹ Full T-cell activation requires signal 2, provided by costimulatory molecules (Fig. 59.1). In the absence of a costimulatory signal, T cells not only will fail to activate but will become refractory to activation. A number of costimulatory molecules are expressed by T cells. One of these is CD28, which

binds to the B7 molecules B7-1 and B7-2 on antigen-presenting cells (see Fig. 59.1).¹ To counterbalance this activation state, cytotoxic T-lymphocyte antigen 4 (CTLA-4), a structural homologue of CD28 expressed by T cells, competes with CD28 for binding to B7-1/B7-2. Because CTLA-4 has higher binding avidity for B7-1/B7-2 than CD28, it acts as a suppressor of T-cell activation.²

ABATACEPT

Abatacept is a soluble human recombinant fusion protein in which the extracellular domain of CTLA-4 is conjugated to the Fc portion of human immunoglobulin. It binds to B7-1/B7-2 and prevents their interaction with CD28 on T cells, thereby modulating costimulation (see Fig. 59.1). In Europe, abatacept, in combination with methotrexate (MTX), is approved for treatment of moderate or severe active RA in adults who have shown an inadequate response to or intolerance of disease modifying antirheumatic drugs (DMARDs) and/or tumor necrosis factor- α (TNF- α) antagonists. Elsewhere, abatacept is also indicated for use as monotherapy in patients with moderate or severe active RA who have had an inadequate response to one or more DMARDs and/or TNF antagonists. It is also approved as a therapy for juvenile idiopathic arthritis. Abatacept is administered as a 30-minute intravenous injection on the 1st, 15th, and 30th days of treatment and thereafter once every 4 weeks. A dose of 500 mg is used for patients weighing less than 60 kg, 750 mg for those weighing 60 to 100 kg, and 1000 mg for those weighing more than 100 kg.

A subcutaneous formulation of abatacept administered weekly at a dose of 125 mg has been approved in the United States and Europe for the treatment of RA. An intravenous loading dose can be used in the subcutaneous regimen but probably is not needed.

Clinical efficacy

Intravenous abatacept

The tolerability and efficacy of intravenous abatacept was initially assessed in RA patients with active disease in whom treatment with DMARDs or etanercept had failed.³ Patients were randomly assigned to receive intravenous infusions of placebo or 0.5 mg/kg, 2 mg/kg, or 10 mg/kg of abatacept monotherapy on days 0, 15, 29, and 57. The primary endpoint was ACR20 response at day 85, and ACR20 criteria were met by 53% of patients receiving 10 mg/kg of abatacept and 31% of patients receiving placebo.

Combination therapy with methotrexate

In a phase 2 double-blind, randomized, controlled trial (RCT), patients who had active RA despite receiving MTX were randomly assigned to receive placebo or abatacept 2 mg/kg or 10 mg/kg.⁴ ACR20 criteria were met in 60% of patients in the 10-mg/kg group versus 35% in the placebo group. Subsequently, the efficacy of abatacept in RA was confirmed in the phase 3 RCT Abatacept in Inadequate Responders to MTX (AIM) in which patients with active RA despite MTX treatment were randomly assigned to receive either placebo or 10 mg/kg of abatacept.⁵ At 6 months, 68%, 40%, and 20% of patients in the abatacept group met ACR20, ACR50, and ACR70 criteria, respectively, compared with 40%, 17%, and 7% in the placebo-treated group. The differences were statistically significant. Along with improvement in symptoms and signs, abatacept-treated patients also had significant improvements in physical function and health-related quality of life as measured by the Health Assessment Questionnaire (HAQ) and Short Form-36 (SF-36), respectively. Abatacept reduced radiographic joint damage progression, with a median change in Genant-modified Sharp scores of 0.25 in the abatacept-treated group compared with 0.53 in the placebo-treated patients.

Fig. 59.1 T-cell activation requires costimulatory signals in addition to T-cell receptor engagement to major histocompatibility complex (MHC) and antigenic peptide. Ag, antigenic peptide; CD40L, CD40 ligand; CTLA-4, cytotoxic T-lymphocyte antigen 4; ICAM-1, intercellular adhesion molecule 1; iCOS, inducible T-cell costimulator; iCOSL, inducible T-cell costimulator ligand; LFA, lymphocyte function-associated antigen; TCR, T-cell receptor.

Therapy after tumor necrosis factor antagonist failure

The Abatacept Trial in Treatment of Anti-TNF Inadequate Responders (ATTAIN) was a 6-month RCT that examined the efficacy and safety of abatacept in patients who had shown an inadequate response to TNF antagonists and had active disease.⁶ At 6 months, ACR20 response criteria were met by 50.4% of abatacept-treated patients versus 19.5% of those in the placebo-treated group. DAS28 remission rates were 10% versus 0.9%, respectively. As in the AIM trial, there was statistically significantly greater improvement in SF-36 scores in those patients treated with abatacept than in those given placebo.

One common dilemma faced by clinicians in treating patients for whom TNF antagonist therapy has failed is whether to start treatment immediately or to allow a washout period before initiating abatacept. This issue was addressed by the Abatacept Researched in Rheumatoid Arthritis Patients with an Inadequate Anti-TNF Response to Validate Effectiveness (ARRIVE) trial,⁷ an open-label study in patients with RA who had shown an inadequate response to TNF antagonists. Patients were randomly assigned to undergo either washout (discontinuation of TNF antagonists for at least 2 months before treatment with abatacept) or direct switching (initiation of abatacept at their next scheduled TNF antagonist treatment). At 6 months, improvement in disease activity was similar in both groups. Importantly, rates of both adverse events and serious adverse events also were similar in the two groups: 78.0% in the washout group versus 79.2% in the direct-switch group and 11.1% in the washout group versus 9.9% in the direct-switch group, respectively. The conclusion of the ARRIVE trial is that a washout period is not necessary in patients who have not responded to TNF antagonists before initiation of treatment with abatacept.

Comparison with tumor necrosis factor inhibitors

Abatacept or infliximab versus placebo, a Trial for Tolerability, Efficacy and Safety in Treating Rheumatoid Arthritis (ATTEST)⁸ evaluated the efficacy and safety of abatacept or infliximab (3 mg/kg) versus placebo in 431 patients with RA who had shown a partial response to MTX. Reduction in DAS28 score was significantly greater with abatacept and infliximab than with placebo (−2.53, −2.25 and −1.48, respectively; $P < .001$) at 6 months. Similar improvement in symptoms and signs, physical function, and health-related quality of life were seen at 1 year. Abatacept showed an advantage over infliximab in the rate of serious infections (1.9% in the abatacept group vs. 8.5% in the infliximab group), discontinuations due to adverse events (3.2% vs. 7.3%, respectively), and serious adverse events (2.6% vs. 3.6%, respectively).

Treatment of early rheumatoid arthritis

The Abatacept Study to Gauge Remission and Joint Damage Progression in MTX-Naïve Patients with Early Erosive RA (AGREE)⁹ was an RCT examining the use of abatacept in patients with early RA who had one of more poor prognostic factors including high levels of C-reactive protein (CRP), radiographic evidence of erosive disease, and seropositivity for rheumatoid factor or anti-citrullinated protein antibody. Patients were randomly assigned to treatment by either intravenous abatacept plus MTX or MTX alone. At 1 year, DAS28 (CRP)-defined remission was achieved more frequently in abatacept-treated patients than in those given placebo: 41.4% versus 23.3%, respectively ($P < .001$). ACR50 and ACR70 criteria were also more frequently achieved in those receiving abatacept than in those given placebo: 57.4% and 42.6% versus 42.3% and 27.3%, respectively. Radiographic damage measured by Genant-modified Sharp scores was statistically significantly lower in patients receiving abatacept plus MTX (0.63) than in those given MTX alone (1.06).

Subcutaneous abatacept

As noted earlier, a subcutaneous formulation of abatacept recently has become available. A number of RCTs have evaluated the efficacy and safety of subcutaneous abatacept in patients with RA.

Combination with methotrexate

A noninferiority trial comparing subcutaneous abatacept 125 mg weekly with intravenous abatacept 10 mg/kg every 4 weeks was conducted in 1457 patients with RA who had active disease despite receiving MTX.¹⁰ ACR20 response criteria were met by 76% of those receiving subcutaneous abatacept and 75.8% of those receiving intravenous abatacept, which confirms that the two formulations have similar efficacy. An open-label, single-arm study in which 123 patients with RA who had been receiving intravenous abatacept long term were switched to subcutaneous abatacept found that, at 3 months, 97.6% of patients were continuing to receive subcutaneous abatacept without loss of efficacy.¹¹

Comparison with tumor necrosis factor antagonists

The Abatacept versus Adalimumab Comparison in Biologic-Naïve Rheumatoid Arthritis (AMPLE) trial, a single-blind RCT involving 646 biologic drug-naïve RA patients being treated with MTX, compared concurrent administration of subcutaneous abatacept 125 mg every week without an intravenous loading dose with concurrent administration of subcutaneous adalimumab 40 mg every 2 weeks¹² in a study powered to demonstrate “noninferiority.” Patients were unblinded to the drug, but the investigators were blinded to the treatment regimen. At 1 year, abatacept plus MTX and adalimumab plus MTX showed similar efficacy, with ACR20, ACR50, and ACR70 response rates of 64.8%, 46.2%, and 29.2%, respectively, for abatacept versus 63.4%, 46%, and 26.2%, respectively, for adalimumab—results that demonstrated comparability or noninferiority. The kinetics of response was similar for both drugs, with similar responses noted by 4 weeks.

Radiographic damage was also similar in the two groups as assessed by the van der Heijde–modified total Sharp score (0.58 and 0.38 in the abatacept and adalimumab groups, respectively). Injection site reactions were less common in abatacept-treated than adalimumab-treated patients (3.8% vs. 9.1%, respectively; $P = .006$). Rates of adverse events, serious adverse events, and infection were similar in the two groups.

Safety

In RCTs, the rate of discontinuation of therapy due to adverse events in patients treated with intravenous abatacept ranged between 1.9% and 8.7%.¹³

Infusion-related reaction

Infusion reactions occur in approximately 10% of patients receiving intravenous abatacept. Most are mild, but rarely anaphylactic reaction occurs. Rate of discontinuation due to infusion-related reaction is low (<1%).

Infection

In the ATTAIN trial, infections were more common in abatacept-treated patients than in placebo-treated patients (37.6% vs. 32.3%, respectively). The majority of infections were mild to moderate. The rate of serious infections was the same in abatacept-treated patients (2.3%) and placebo-treated patients (2.3%).⁶ In the AIM trial, serious infections were more frequent in abatacept-treated patients than in placebo-treated patients: 3.9% versus 2.3%, respectively.⁵

The Abatacept Study of Safety in Use with Other RA Therapies (ASSURE), a large-scale safety study of abatacept in patients concurrently taking a

traditional DMARD and/or anticytokine agent,¹⁴ found that serious infection occurred in 2.6% of patients received abatacept plus a DMARD versus 1.7% of patients taking a DMARD only. The rate of serious infection was higher in patients taking abatacept with an anticytokine agent (5.8%) than in patients taking an anticytokine agent only (1.6%). Hence combining abatacept with anticytokines is not recommended in routine clinical practice.

Tuberculosis

Screening for tuberculosis is recommended before initiation of any biologic therapy for RA since reactivation of latent tuberculosis has been reported in patients treated with TNF antagonists.¹⁵ In RCTs of abatacept, all patients were screened for latent tuberculosis. In long-term extension studies of RCTs, including AIM and ATTEST, tuberculosis was reported in fewer than 1% of cases.^{5,6}

Vaccination

Abatacept was shown to reduce the protective humoral response to influenza vaccine in 11 RA patients receiving abatacept and DMARDs compared with 33 age-matched RA patients taking MTX and 55 healthy controls.¹⁶ Humoral response to vaccination was observed in 9% of RA patients receiving abatacept and DMARDs compared with 58% of RA patients receiving MTX and 69% of healthy controls ($P < .01$).

Malignancy

The risk of malignancy is a concern with the use of immunomodulatory treatment, since increased incidence of cancer has been reported with immunosuppressive drugs. The incidence of malignancy in patients with RA receiving abatacept in RCTs and open-label studies has been compared with that in patients receiving DMARDs in observational studies by Simon and colleagues¹⁷ and Khraishi and colleagues.¹³ The overall incidence was 0.63 (95% confidence interval 0.46 to 0.84) per 100 patient-years in abatacept-treated patients compared with 0.63 (95% confidence interval 0.26 to 1.5) patient-years in placebo-treated patients. However, the number of patient studied so far is too small for a definitive conclusion to be drawn.

Subcutaneous abatacept

In clinical trials, the rates of adverse events and serious adverse events were similar in patients treated with subcutaneous abatacept and those treated with intravenous abatacept: 65.2% and 4.9% versus 67.0% and 4.2%, respectively. Injection site reactions associated with subcutaneous abatacept therapy are mostly mild and occurred in fewer than 4% of patients.

Immunogenicity

Overall, the immunogenicity of abatacept is low. In phase 3 RCTs, antibodies against intravenously administered abatacept developed in fewer than 3% of patients.¹³ Abatacept induced antibodies in 1.1% of patients treated with the subcutaneous formulation compared with 2.6% of intravenously treated patients.¹⁰ Switching from intravenous to subcutaneous abatacept has limited effect on immunogenicity.¹¹ Immunogenicity was seen in 8 of 123 patients after switching, of whom 6 tested positive before changing to subcutaneous injection. In a follow-on study in which the effects of withdrawal and reintroduction of abatacept were assessed, a stop-start regimen was found to have little impact on efficacy, safety, and immunogenicity.

Biologic effects

Abatacept treatment is associated with changes in the number of CD4+ and CD8+ circulating T lymphocytes in the blood. Furthermore, reduction in interferon- γ expression in synovial tissue suggested reduction in T-cell activation. In animal models of autoimmune diseases, costimulatory blockade induces anergy/tolerance. Hitherto, anergy/tolerance had not been demonstrated in clinical trials of patients with RA. However, an exploratory trial in which patients with undifferentiated inflammatory arthritis were randomly assigned to receive either placebo or abatacept therapy for 6 months found that, at the end of 1 year, numerically more placebo-treated patients (66.7%) than abatacept-treated patients (46.2%) developed RA, although the difference was not statistically significant.¹⁸

Anti-T-cell strategies in rheumatoid arthritis

Strategy	Agent(s)
T-cell subset depletion	Anti-CD7, ²⁰ CD5-plus (XOMA Corp, Berkeley, Calif.), ²¹ IL2-DAB (Pfizer, New York), ²² Campath-1H (anti-CDw52, Alemtuzmab, Sanofi, Paris), ²³⁻²⁵ and anti-CD4 monoclonal antibodies (Centocor, Malvern, Pa.) ²⁶⁻³²
T-cell immunomodulation	Nondepleting anti-CD4 monoclonal antibodies: IDEC-CE9.1/SB-210396 (SmithKline Beecham, Philadelphia), ³³ 4162W94 (Glaxo Wellcome, London) ²⁷ MTRX1011A (Genentech, South San Francisco, Calif.) ³⁴
Vaccination	T cells ^{35,36} T-cell receptors (IR501, Immune Response Corp., New York) ³⁷ MHC peptides: HLA-DRB1*0404/B1*04041 peptide (Anergen, part of GSK, UK) ³⁸ and HLA-DRB1*0404/peptide from HC gp-39 (AG4263) ³⁹
Oral tolerance	Chicken collagen ⁴⁰⁻⁴⁵ Bovine collagen ⁴⁶⁻⁴⁸
Increasing CD4+ regulatory T-cell number	CD28 superagonist (TGN1412, TeGenero Immuno Therapeutics, Würzburg, Germany) ⁴⁹

HC gp-39, human cortiloge glycoprotein 39; IL2-DAB, interleukin-2 diphtherio fusion protein; MHC, major histocompatibility complex.

Conclusions

RCTs of abatacept have shown that selective modulation of T-cell costimulation is an effective treatment strategy in patients with RA with consistent efficacy and safety profile across many clinical studies.

OTHER T-CELL-DIRECTED THERAPIES

Ideally, T-cell-directed therapy should target, primarily or exclusively, the arthritogenic T cells. Clearly, such specific therapy would be less toxic than a general anti-T-cell therapy. However, this type of therapy is more difficult to achieve, especially in established disease, since the arthritogenic peptide- and disease-specific T cells in RA remain unknown. Both depletion and immunomodulation therapies against T cells have been tested in RA (Table 59.1). The development of these strategies has been not continued due to either toxicity or limited efficacy.

FUTURE OF T-CELL TARGETING

In animal models, nonmitogenic, nondepleting anti-CD3 monoclonal antibody can induce immunologic tolerance.¹⁹ Research into the use of a nonmitogenic, nondepleting anti-CD3 monoclonal antibody in RA is being conducted.

CONCLUSION

Current evidence suggests that T cells are pathogenic in RA and play an important role in sustaining synovitis, even in established disease. Modulation of T-cell activity by costimulatory blockade suppresses inflammation and improves disease. In animal models of RA, immunomodulation of T cells can indeed produce prolonged disease remission; however, this has yet to be demonstrated in human disease.

B-cell depletion

■ EDWARD M. VITAL ■ SHOUVIK DASS ■ PAUL EMERY

- B-cell depletion therapies are used for the treatment of various rheumatic diseases, and rituximab is currently the agent most widely used.
- Rituximab depletes B cells by targeting CD20, although the level of B-cell depletion varies between patients.
- Rituximab is licensed for the treatment of severe, active rheumatoid arthritis (RA) in patients who have had an inadequate response to anti-tumor necrosis factor therapy and for the treatment of antineutrophilic cytoplasmic antibody-associated vasculitis.
- For RA, rituximab is given as a course of two infusions, which may be repeated after 6 months if disease activity is ongoing or later if and when disease activity worsens after the initial response; a similar paradigm has been adopted for connective tissue diseases, but the duration of response may be longer than for RA.
- The safety profile of rituximab does not indicate a significant increase in risk for infection, although lower than normal levels of immunoglobulin develop in some patients after several courses. Isolated cases of progressive multifocal leukoencephalopathy have been reported.
- Rituximab has been used for the treatment of systemic lupus erythematosus and Sjögren syndrome, although further studies are required in this area.

INTRODUCTION

Therapeutic B-cell depletion with monoclonal antibodies was originally developed as a treatment of B-cell malignancies and is now being used for the management of several rheumatic diseases.

After an initial case report of improvement of rheumatoid arthritis (RA) in a patient treated with a combination of rituximab and other chemotherapeutic agents,¹ promising results in a small case series of patients² led to the conduct of pivotal multicenter, randomized, controlled trials.

B-cell depletion targeted at CD20 is temporary because of the sparing of stem cells. An initial expectation of many was that temporary clearance of B cells would be sufficient to eliminate the pathogenic clones and lead to sustained remission after repopulation with a new diverse population of B cells. However, in all rheumatic diseases treated, patients ultimately relapse, albeit after a variable interval following B-cell repopulation, and repeated cycles are required to recapture response. Furthermore, clinical responses to depletion vary, thus implying potential pathogenic or pharmacodynamic differences between subgroups of patients.

The response to rituximab therefore established a different therapeutic paradigm than for other immunosuppressive therapies. Clinical questions of importance include the efficacy and safety of repeated cycles of therapy, choosing an appropriate dose and retreatment interval, and defining subgroups of patients likely to respond.

ROLES OF B CELLS IN AUTOIMMUNE DISEASES

B lymphocytes are generated in bone marrow with specific antigen reactivity and negative selection against autoreactive B cells. They are then released into the circulation as transitional cells and ultimately become mature naive

B cells. Naive B cells become activated on meeting their cognate antigen and then participate in germinal center reactions, which involve an interaction of B and T cells arising from B-cell presentation of the antigen, along with other co-stimulatory molecules. In certain instances, B cells may be activated in a T cell-independent manner, such as by bacterial polysaccharides via B-cell and Toll-like receptors. However, HLA associations imply that this is less relevant to the rheumatic diseases usually treated by B-cell depletion.

B-cell activation may lead to multiple memory and effector mechanisms. Memory B cells are generated, as well as short- and long-lived plasma cells that secrete antibody.³ Memory B cells contribute to immune memory by requiring a lower threshold for reactivation on reencountering their cognate antigen and thereafter rapidly differentiating into plasma cells. Short-lived plasma cells provide an immediate antibody response that may be generated without T-cell help. Long-lived plasma cells persist for many years after migrating to bone marrow and hence contribute to both immune memory and maintenance of normal immunoglobulin levels. Finally, T-cell activation following interaction with B cells may activate other effector mechanisms besides B and plasma cells, such as release of inflammatory cytokines.

Hence, B cells may mediate autoimmune disease by production of autoantibodies or immune complexes via plasma cells; by presenting antigen to T cells, which leads to T cell-mediated inflammation; or by producing inflammatory cytokines.

RA is associated with the autoantibodies rheumatoid factor (RF) and anti-cyclic citrullinated protein antibody, and T-cell activation in RA may require antigen presentation by B cells.⁴ Autoantibodies may be expressed years before clinical symptoms,⁵ and their exact role in synovitis remains unclear. Systemic lupus erythematosus (SLE) and Sjögren syndrome are associated with antibodies to nuclear components. There is evidence of immune complex deposition at sites of disease, but again, B cells may also have antibody-independent effects, at least in animal models.⁶ In antineutrophilic cytoplasmic antibody (ANCA)-associated vasculitis, antibodies are directed against the proteinase-3 and myeloperoxidase located in neutrophils and neutrophil extracellular traps, which may be found in the glomerulus.

B-cell depletion with rituximab generally reduces autoantibody titers, thus indicating their production by short-lived plasma cells, and targeting of long-lived plasma cells is not necessary in most patients. However, antibody status and changes only partially explain the clinical response.

Targeting CD20

CD20 is a 33- to 37-kDa, nonglycosylated phosphoprotein expressed on the surface of mature naive B cells that have exited the bone marrow to enter blood. It is expressed neither on stem cells nor on plasma cells that have returned to bone marrow (Fig. 60.1). This selective expression on mature B cells but not on precursors such as stem cells or on antibody-secreting plasma cells makes it an attractive target, particularly from the point of view of theoretic safety concerns. Depletion via CD20 permits B-cell regeneration and prevents reduction of immunoglobulin levels, at least with initial therapy. Furthermore, on binding antibody, CD20 did not initially appear to be shed from the cell surface or be detectable in serum and is not internalized.⁷ However, evidence from hematology patients has shown that targeted epitope expression may decline after the infusion of monoclonal antibodies. It has been demonstrated *in vitro* that rituximab/CD20 complexes may be removed from B cells by THP-1 monocytes via FcγR, thereby preventing their killing—"CD20 shaving."⁸ CD20 appears to have no natural ligand, and CD20 knockout mice display an almost normal phenotype,⁹ but *in vitro* evidence suggests that it regulates intracellular calcium.

Fig. 60.1 During normal maturation and differentiation of B lineage cells surface marker expression changes. These markers are used for B cell subset identification in flow cytometry. CD20 expression spares Pro B cells and plasma cells in bone marrow, accounting for recovery of B cell numbers and preservation of immunoglobulin titres. BLYS/APRIL receptor expression changes reflect the changing dependence of B cells on these survival factors as the differentiate (see text for details).

Rituximab

Rituximab, the first anti-CD20 monoclonal antibody to be used therapeutically, consists of fusion of the light- and heavy-chain variable regions of a murine antihuman monoclonal anti-CD20 antibody with human immunoglobulin κ light-chain and $\gamma 1$ heavy-chain constant regions.¹⁰ It was originally developed for the treatment of refractory CD20+ B-cell non-Hodgkin lymphoma (NHL)¹¹ and has demonstrated efficacy against other B-cell malignancies such as B-cell chronic lymphocytic leukemia and diffuse large B-cell lymphoma. B-cell killing *in vivo* is achieved by antibody-dependent cell-mediated cytotoxicity (ADCC) by effector cells, complement-dependent cytotoxicity, and apoptosis. ADCC is thought to be its most important mechanism of cell killing¹² (Fig. 60.2).

Rituximab is formulated for intravenous administration over a period of several hours. Clinical pharmacokinetic data are available for two consecutive doses of 500 mg (RTX500) and two doses of 1000 mg (RTX1000) given on days 1 and 15. The mean terminal elimination half-life ranged from 16 to 16.5 days (after the second infusion) for the former dose and 18 to 21 days for the latter. No difference in pharmacokinetics was seen between the first and second cycles of treatment. Because of the risk for infusion-related reactions, rituximab should be administered in clinical environments in which full resuscitation facilities are available, although severe infusion reactions are uncommon in the treatment of autoimmune diseases. Prophylaxis with paracetamol (1 g) and diphenhydramine HCl (25 to 50 mg or equivalent dose of a similar agent) should be initiated 30 to 60 minutes before infusion of rituximab.¹³

Rituximab biosimilars

Roche's patents on rituximab expire in 2014-2015, and several manufacturers are developing "biosimilars"—molecules based on the same amino acid sequence but potentially different manufacturing processes (and therefore posttranslational modifications) in an attempt to match the overall characteristics of marketed rituximab as closely as possible.

Second- and third-generation anti-CD20 molecules

Ofatumumab is a fully human anti-CD20 antibody that binds to a different epitope than rituximab does; it is licensed for resistant chronic lymphocytic leukemia and has shown evidence of efficacy in treating RA.¹⁴ Obinutuzumab is a humanized anti-CD20 antibody that also binds a different epitope than rituximab does; it has phase 1 efficacy and safety data published for NHL.¹⁵ Ocrelizumab is a humanized anti-CD20 antibody that binds to an overlapping CD20 epitope to rituximab with increased ADCC and reduced complement-dependent cytotoxicity, also developed by Roche. It met endpoints in clinical trials involving RA and was used in trials for SLE.¹⁶ Development for these indications ended after evidence of an increased rate of

Fig. 60.2 There are three possible mechanisms of cell killing for anti-CD20 antibodies: ADCC (antibody-dependent cell-mediated cytotoxicity); Complement-dependent cytotoxicity and induction of apoptosis. However, there is only indirect evidence for which is most important *in vivo*. ADCC is generally thought to be the predominant mechanism. Cell killing depends on Fc-gamma receptor bearing NK cells or monocytes following the binding of rituximab to CD20. NK, natural killer.

opportunistic infection. The drug is being still developed for the treatment of multiple sclerosis.¹⁷

Efficacy for rheumatoid arthritis

Open-label series initially reported regimens containing variable doses of rituximab, cyclophosphamide, and high-dose corticosteroid to be efficacious. The efficacy of rituximab has since been tested in a series of randomized controlled trials¹⁸⁻²³ (Table 60.1). In all these studies rituximab was administered as two infusions 2 weeks apart, each preceded by 100 mg

■ TABLE 60.1

Summary of efficacy data in rituximab in rheumatoid arthritis: randomized controlled trials

Study	Population	Randomization	Endpoints	Key findings	Reference
Edwards et al.	MTX-IR RF positive	1: MTX (n = 40) 2: RTX1000 (n = 40) 3: RTX1000 + CyP (n = 41) 4: RTX1000 + MTX (n = 40) All groups had PO-CS and IV-CS	1: ACR50 at wk 24 2: DAS28, EULAR, and ACR responses at 24 and 48 wk	All RTX arms superior to MTX at 6 mo Only arms 3 and 4 significantly superior at 12 mo B cells depleted in all RTX groups for 24 wk RF reduced; total Ig remained stable	18
DANCER	MTX-IR or TNF-IR RF/CCP positive or negative	1: Placebo 2: Placebo + IV-CS 3: Placebo + IV-CS + PO-CS 4: RTX500 5: RTX500 + IV-CS 6: RTX500 + IV-CS + PO-CS 7: RTX1000 8: RTX1000 + IV-CS 9: RTX1000 + IV-CS + PO-CS All groups had MTX Total N = 465 Retreatment on relapse	1: ACR20 at wk 24 2: DAS28, EULAR, and ACR responses at wk 24; HAQ, FACIT-F, safety, Ig, HACA	All RTX arms superior to placebo Time to best response 12-24 wk Numerically higher ACR70 and EULAR good response in RTX 1000 groups vs. RTX 500 CS did not influence efficacy endpoints IV-CS reduces infusion reactions, no added benefit with PO-CS HACA rate: placebo = 0.7%, RTX 500 = 4.2%, RTX 1000 = 2.7%, but no clinical sequelae	19
REFLEX	TNF-IR RF/CCP positive or negative	1: Placebo + MTX (n = 209) 2: RTX1000 + MTX (n = 311) All groups had PO-CS and IV-CS Retreatment on relapse	1: ACR20 at wk 24 2: DAS28, EULAR, and ACR responses at wk 24 Other: HAQ, FACIT-F, radiographic, safety	RTX superior to placebo: ACR20 = 51% vs. 18% Trend to less progression in total Genant-modified Sharp score Significantly less progression in joint space narrowing score Nonserious AEs other than infusion reactions balanced Serious infections: placebo = 3.7, RTX = 5.2/100 patient-yr	20
SERENE	MTX-IR RF/CCP positive or negative	1: Placebo + MTX 2: RTX500 + MTX 3: RTX1000 + MTX Retreatment from wk 24 unless in remission	1: ACR20 at wk 24 2: DAS28, EULAR, and ACR responses; HAQ, SF36, FACIT-F	Confirmed similar level of efficacy at wk 24 as REFLEX study Further improvement in response rates following retreatment No difference between rituximab doses Better responses if RF or CCP positive at baseline	21
MIRROR	MTX-IR or TNF-IR RF/CCP positive or negative	1: RTX500 then RTX500 2: RTX500 then RTX1000 3: RTX1000 then RTX1000 Treatment at 0 and 24 wk in all patients All patients received MTX	1: ACR20 at wk 48 2: DAS28, EULAR, and ACR responses; HAQ, SF36, FACIT-F	Numerically higher ACR response at 48 wk in arm 3 vs. other 2 arms Statistically better EULAR response at 48 wk in arm 3 46% of ACR20 nonresponders at 24 wk responded at 48 wk (arm 3) Fewer patients had worse response at 48 wk in arm 3	22
IMAGE	MTX naive RF-negative patients needed erosions to enroll	1: Placebo + MTX 2: RTX500 + MTX 3: RTX1000 + MTX Retreatment from wk 24 unless in remission	1: Change in mTSS at wk 52 Other: major clinical response (maintenance of ACR70 >6 mo). DAS28, EULAR, and ACR responses; HAQ, SF36, FACIT-F	RTX + MTX superior to MTX alone in MTX-naive RA ACR and EULAR responses not affected by RTX dose mTSS progression only significantly better with RTX 1000	23

ACR, American College of Rheumatology; AE, adverse event; CCP, cyclic citrullinated protein; CS, corticosteroid; CyP, cyclophosphamide; DAS28, 28-joint disease activity score; EULAR, European League Against Rheumatism; FACIT-F, Functional Assessment of Chronic Illness Therapy–Fatigue subscale; HACA, human antichimeric antibody; HAQ, Health Assessment Questionnaire; Ig, immunoglobulin; IV-CS, intravenous methylprednisolone 100 mg days 1 and 15; mTSS, total Genant-modified Sharp score; MTX, methotrexate; PO-CS, oral prednisolone 60 mg days 2-7, 30 mg days 8-14; RA, rheumatoid arthritis; RF, rheumatoid factor; RTX500, 2 × 500 mg rituximab; RTX1000, 2 × 1000 mg rituximab; TNF, tumor necrosis factor.

methylprednisolone. However, rituximab doses, other concomitant therapies, and retreatment intervals varied.

Rituximab was licensed by the U.S. Food and Drug Administration (FDA) and European Medicines Agency for the treatment of severe active RA in patients with an inadequate response to anti-tumor necrosis factor (TNF) therapy.

Radiographic outcomes

Data on radiographic progression following rituximab are available from the REFLEX²⁰ and IMAGE²³ studies. The patient populations in these studies were quite different. The former enrolled patients with a relatively long disease duration (approximately 12 years) who had already had an

inadequate response to anti-TNF therapy. In the latter, patients had much a shorter disease duration (mean duration, 0.9 months) and had not yet received methotrexate. In the REFLEX study, patients were taking methotrexate and were then randomized to receive either rituximab (1000 mg for two doses) or placebo. Retreatment with the same dose was given when patients flared after their initial response; patients randomized to placebo could be given rescue treatment with rituximab, but for the purposes of analysis, such patients were still considered part of the “placebo” group. Radiographs of patients’ hands and feet were obtained at baseline, week 24, and week 56 and scored with the Genant-modified Sharp method. Patients who received rituximab had significantly less radiographic disease progression than did those who received placebo. The mean change from baseline

in the total Genant-modified Sharp score at week 56 was significantly lower in patients treated with rituximab (1.00 versus 2.31, rituximab versus placebo, $P = .005$); changes in erosion scores (0.59 versus 1.32, rituximab versus placebo, $P = .011$) and joint space narrowing (0.41 versus 0.99, $P < .001$) were significantly in favor of rituximab. Patients treated with rituximab whose clinical outcomes were no better than those receiving placebo still had less radiographic progression.

The IMAGE study of methotrexate-naïve patients with early RA measured similar outcomes in 715 patients randomized equally to three arms: methotrexate alone, methotrexate plus RTX500, or methotrexate plus RTX1000.²³ At 52 weeks, patients who received higher-dose rituximab (i.e., 2×1000 mg, repeated at 6 months in patients not in remission and given to patients in remission at 6 months if and when their disease activity score [DAS] later worsened) had significantly lower changes in the mean total Sharp score (mTSS) (0.359 versus 1.079, $P < .001$), and more patients had no progression in the mTSS when treated with that dose of rituximab (63.5 versus 53.4, $P < .05$). Although statistically significant differences were not observed between patients receiving methotrexate alone and those treated with the lower dose of rituximab, a numeric difference favored the lower dose of rituximab over methotrexate alone.

Outcome of repeated cycles

Patients from the original large randomized studies were followed in open-label extension studies. Patients who were deemed to be responders (by predefined criteria) were eligible for retreatment with a further cycle of two infusions of RTX1000 with preceding methylprednisolone if they subsequently had deterioration in disease activity. Data for up to five courses of therapy²⁴ are reported. The median treatment interval between the first, second, and third courses in patients with previous anti-TNF exposure remained stable at approximately 30 weeks (Fig. 60.3). Clinical responses were also sustained. American College of Rheumatology (ACR) and DAS responses were similar after the first and second courses, and the proportions of patients achieving ACR70, 28-joint Disease Activity Score (DAS28) low disease activity (DAS28 <3.2), and DAS28 remission (DAS28 <2.6) increased after the second course. The change in DAS28 from baseline after each course was consistent, thus implying a cumulative progressive reduction in disease activity with repeated treatment.

The most commonly used paradigm for rituximab therapy, therefore, is repeated therapy if a patient deteriorates after initially improving. Inherent in this paradigm is a degree of instability with potential clinical implications such as more short-term steroid use, and this may also potentially be detrimental to long-term outcomes. Results from the studies listed in Table 60.1 have been compared. Control of disease activity and safety both

appeared to be better in patients receiving fixed retreatment protocols, although this is confounded by differences in inclusion criteria.

Effect of rituximab dose

Existing data from four randomized controlled trials that used both rituximab doses have yielded conflicting information on their comparative efficacy, possibly because these studies recruited different patient populations and had different retreatment frequencies and outcome measures. The DANCER study recruited patients with established RA after failure of methotrexate or one or more TNF inhibitors and showed that single cycles of RTX500 or RTX1000 were both superior to placebo.¹⁹ There was no statistical comparison between these arms, but rates of “high-hurdle” endpoints were numerically higher after RTX1000 (European League Against Rheumatism [EULAR] good response: 14% versus 28%; ACR70: 13% versus 20% for RTX500 and RTX1000, respectively).¹⁹ The SERENE study recruited patients who had previously failed methotrexate only and used rituximab every 6 months unless in remission.²¹ This study found no substantive or significant differences between rituximab doses. Interestingly, however, the ACR70 rate was not significantly superior to placebo at either dose of rituximab in this study, in contrast to DANCER.¹⁹ The MIRROR study recruited patients who had failed methotrexate and either none or one TNF inhibitor and were treated with rituximab at baseline and 6 months.²² This study found a significant difference in the EULAR response rate between RTX500 and RTX1000 at 52 weeks (72% versus 88%; $P < .05$). However, ACR responses did not differ except in the subgroup previously treated with anti-TNF.²² The IMAGE study recruited methotrexate-naïve patients with early RA and included a radiographic primary outcome measure.²³ Clinical responses were not significantly different. However, only the RTX1000 group demonstrated significant inhibition of radiographic progression in comparison to placebo at 24 and 52 weeks. The mean change in total Sharp score was also significantly less in the RTX1000 than in the RTX500 group at 52 weeks.²³

One study reported that B-cell and plasmablast numbers, rather than dose per se, correlated with clinical response. Patients with low numbers of plasmablasts at baseline had complete plasmablast depletion and a good clinical response with RTX500.²⁵

Six months after treatment, B cells are approximately 10 times lower than at baseline and in many cases remain undetectable by conventional methodologies. Lower doses of rituximab might be equally effective in repeated cycles.²⁶

Retreatment of nonresponse

A single course of rituximab does not usually normalize autoantibody titers, and mechanistic studies demonstrate the persistence of B-lineage cells in peripheral blood and synovium in clinical nonresponders. One study targeted patients with an inadequate response to an initial cycle of rituximab for retreatment at 6 months in an attempt to increase B-cell and plasmablast depletion. Increased B-cell depletion was seen, and 72% of the nonresponders became EULAR moderate or good responders after retreatment, with the duration of response being equivalent to that of the initial responders.²⁷

Concomitant disease-modifying antirheumatic drugs and corticosteroids

The DANCER study reported that premedication with intravenous steroids appeared to reduce acute infusion-related reactions.¹⁹ However, the use of oral corticosteroids appeared to be unnecessary in terms of improving long-term outcomes and had no effect on infusion reactions after the second infusion. Steroids did improve the initial clinical response at 4 weeks after therapy; subsequently, clinical improvement (ACR20 response) continued before reaching a plateau at 12 weeks. The EULAR consensus statement regarding rituximab²⁸ recommends advising patients that they may experience an immediate but transient benefit after therapy followed by slower response that may take up to 12 weeks to become apparent. An open-label study in which premedication with oral instead of intravenous steroids was substituted suggested that the incidence of infusion reactions was not dissimilar between the two treatment approaches.²⁹

The DANCER study demonstrated the benefit of methotrexate in prolonging response. The duration of B-cell depletion after rituximab appears to be unrelated to the concomitant use of methotrexate,³⁰ although the data provided by highly sensitive flow cytometry to optimize detection of plasmablasts demonstrated a difference in immediate depletion.³¹ Use of other concomitant disease-modifying antirheumatic drugs (DMARDs)—in particular, leflunomide—in a small number of patients has been reported to be safe and effective and reproduces the effect of methotrexate on peripheral B-cell subsets.³²

Fig. 60.3 Mean time to retreatment of patients who received up to three cycles of rituximab in long-term extensions of phase 2 DANCER and REFLEX studies according to previous TNF exposure. Error bars represent 95% confidence intervals. TNF, tumor necrosis factor. (From Keystone E, Fleishmann R, Emery P, et al. Safety and efficacy of additional courses of rituximab in patients with active rheumatoid arthritis: an open-label extension analysis. *Arthritis Rheum* 2007;56:3896-908.)

Mechanism-of-action studies and prediction of response

Antibody status

The phase 2a study included only patients who were positive for RF; in DANCER, 380 patients were RF positive and 85 were RF negative; and in REFLEX, both RF-positive (81%) and RF-negative patients were also included. A meta-analysis of these studies indicated a modest additional increase in benefit in seropositive over seronegative patients—the reduction in the DAS28–erythrocyte sedimentation rate was on average 0.35 units greater in the former group (95% confidence interval, 0.12 to 0.84).³³ The effect of serologic status may be greater in patients who have received one or more anti-TNF agents than in those who are methotrexate naïve. Another study also reported that RF or anti-CCP antibodies and higher titers of total serum IgG were associated with response to rituximab.³⁴

Peripheral blood B-cell studies

Early studies indicated no correlation between total B-cell numbers and clinical response to rituximab.³⁵ A flow cytometry protocol that was optimized for detection of plasmablasts demonstrated that a higher number of these cells at baseline was associated with an inferior response to rituximab at 6 months.³⁶ Persistence of plasmablasts after the first infusion of rituximab was also associated with an inferior clinical response.³⁷

Genetic studies

Genetic studies have focused on Fcγ receptor polymorphisms and B-cell survival factors. The FCGR3A-158V/F polymorphism seemed to be associated in one study involving RA.³⁸

Safety in treating rheumatoid arthritis

No new safety signals have emerged from the use of rituximab for RA when compared with the extensive data available from hematology and oncology practice.³⁹

Screening before therapy

Patients should be screened by eliciting a history of chronic or concomitant comorbidity—with a focus on cardiovascular and pulmonary disease and infections. No increased risk for tuberculosis has been observed in lymphoma patients treated with rituximab.³⁹ Although screening for latent tuberculosis is not required, most rheumatologists routinely screen for it before starting rituximab therapy. Screening for hepatitis B infection is recommended because of reactivation of infection with fulminant hepatitis after rituximab therapy.⁴⁰ Patients with hepatitis B have been treated successfully with antiviral prophylaxis while taking rituximab,⁴⁰ and patients with hepatitis C have been treated without any prophylaxis.

Infusion reactions

Infusion reactions are the most frequent adverse events observed with rituximab therapy and include pruritus, urticaria, pyrexia, throat irritation, and hypotension and hypertension, but these reactions are usually mild to moderate in severity. It has been suggested that these reactions are due to release of cytokines following B-cell lysis.⁴¹ Such symptoms affect up to 30% of patients, but it should be noted that the incidence following the second infusion is much lower,¹⁹ possibly because B-cell numbers are already significantly reduced by the first infusion. The lower rate of infusion reactions in patients with RA than in those with NHL may also be related to this because the latter group often has a heavier B-cell load before therapy. A small number of patients (<1%) experienced serious infusion reactions (anaphylaxis and bronchospasm).

Intravenous steroid administration before infusion of rituximab reduced infusion reactions from 37% to 29% in patients receiving a first infusion of 1000 mg rituximab.¹⁹ Repeated courses are associated with fewer infusion reactions.²⁴ Infusion reactions can be managed with additional paracetamol, antihistamines, and if required, bronchodilators and steroids.

Infections

Rituximab therapy should be delayed until any active infections have resolved. Most infections after rituximab were minor and largely consisted of upper respiratory or urinary tract infections. There was a slight increase in serious infections (5.2 versus 3.7 per 100 patient-years) over placebo in the REFLEX trial. Limited data suggest an increased risk for opportunistic infections. A small number of patients with previous tuberculosis or a positive Mantoux test have been treated without reactivation of disease. A cumulative reduction in immunoglobulin levels occurs with repeated cycles of therapy. After a third course of rituximab, 23.5% of patients have lower than normal level of IgM (Fig. 60.4). No change was found in the incidence

Fig. 60.4 Mean rate of serious infections per 100 patient-years in patients who received up to four cycles of rituximab in long-term extensions of phase 2 DANCER and REFLEX studies according to previous tumor necrosis factor exposure. Error bars represent 95% confidence intervals. (From Keystone E, Fleischmann R, Emery P, et al. Safety and efficacy of additional courses of rituximab in patients with active rheumatoid arthritis: an open-label extension analysis. *Arthritis Rheum* 2007;56:3896-908.)

of infections in these patients before and after IgM fell below the normal limit. After cycles 3 and 4, approximately 5% of patients have low levels of IgG at any time. Data from the French AIR registry, however, indicate an increased rate of serious infections in patients with a low IgG level before receiving a first or repeated cycle of rituximab.⁴²

Vaccination responses and immunization following rituximab

A randomized controlled study (SIERRA) compared immunization responses in patients treated with combination rituximab and methotrexate and those receiving methotrexate alone.⁴³ All patients had similar effective responses to recall antigen (tetanus) and the ability to mount a cutaneous delayed-type hypersensitivity response to *Candida albicans* was similarly preserved, but responsiveness to pneumococcal vaccine (a polysaccharide antigen response) and a neoantigen (keyhole limpet hemocyanin) was diminished in rituximab-treated patients. It is recommended that vaccination be completed 4 weeks before rituximab therapy.

Progressive multifocal leukoencephalopathy

A small number of cases of progressive multifocal leukoencephalopathy (PML) have been reported in patients receiving rituximab for autoimmune diseases.⁴⁴ The incidence of PML is higher in patients with autoimmune rheumatic disease and in those receiving any form of immunosuppression. The incidence of PML in patients with RA treated with rituximab is quoted as being 1 in 25,000.⁴⁵ PML should be considered in the differential diagnosis of any patient treated with rituximab who is noted to have a change in neurologic status.⁴⁶

With regard to other potential side effects (malignancy, cutaneous and pulmonary) that have been observed with other biologic agents, limited data are available. No increased risk for malignancy was identified in one national cohort study of patients who had received one course of rituximab.⁴⁷ There have been case reports of psoriasis developing after treatment with rituximab.⁴⁸

Rituximab: use for connective tissue diseases

Rituximab has also been used increasingly widely for the treatment of connective tissue diseases. Randomized studies have been conducted in patients with SLE, primary Sjögren syndrome (pSS), and ANCA-associated vasculitis (AAV), and there are also considerable data from open-label series, often in patients with disease resistant to other therapies.

Systemic lupus erythematosus

Rituximab is used for SLE, but to date randomized controlled trials have not been positive. All open-label studies report a high degree of efficacy, including larger single-center series with a wide spectrum of

manifestations,^{49,50} a multicenter registry,⁵¹ and a systematic review of renal disease.⁵² Open-label series have reported rituximab to be efficacious for a range of disease manifestations,⁵³ including lupus nephritis, arthritis, hematologic disease (immune thrombocytopenia and autoimmune hemolytic anemia), cutaneous involvement, serositis, and cardiac, respiratory, and cerebral organ involvement. In these series most patients had received immunosuppression with DMARDs, including (but not always) cyclophosphamide, before treatment with rituximab. A variety of doses—usually either two infusions of 1 g rituximab or four infusions of 375 mg/m²—were used, as were different combinations of DMARDs, as well as rituximab monotherapy. Time to relapse is highly variable in SLE, with a subset of patients having much longer periods of remission (several years) in comparison to RA. Longer responses have been associated with negative antibodies to extractable nuclear antigens normal C3, and delayed repopulation of plasmablasts and memory B cells.^{50,54} Repeated cycles appear to be effective.⁵⁵

It has therefore been surprising that the first randomized controlled trial for SLE—“EXPLORER”—failed to meet any of its primary or secondary endpoints.⁵⁶ This discrepancy may be related to the endpoints used in the EXPLORER study and to the use of an active comparator. Patients were randomized to a high-dose corticosteroid regimen with tapering over a 6-month period combined with a conventional immunosuppressant with or without two infusions of rituximab at 0 and 6 months. The primary endpoint required patients to first meet a low-disease activity landmark at 6 months and then not flare in the second 6 months. However, the number of patients meeting the initial landmark in either arm was low, and in those who did meet that landmark, the subsequent flare rate was low even in the control arm. *Post-hoc* analyses of this study showed differences between rituximab and placebo in patients whose concomitant immunosuppressant was methotrexate, in patients of African ancestry, and in the British Isles Lupus Assessment Group A flare rate. A second randomized controlled trial of lupus nephritis also failed to meet its endpoints, but again, use of an active comparator may make interpretation difficult. These studies may therefore have been suggested to have underestimated the benefits of rituximab for SLE.

Sjögren Syndrome

Open-label studies of rituximab indicated improvement in sicca symptoms and objective measures, as well as in the histologic changes associated with MALToma.⁵⁷ A pilot randomized, double-blind, placebo-controlled trial of rituximab for pSS did show greater improvement in fatigue scores with rituximab than with placebo.⁵⁸

Vasculitis

Rituximab has been approved by the FDA for the treatment of AAV. A randomized, double-blind, double-dummy, noninferiority trial, the Rituximab in ANCA Associated Vasculitis study, was designed as a noninferiority

study to compare rituximab (four doses of 375 mg/m² intravenously) with cyclophosphamide (2 mg/kg/day orally) for 3 months followed by azathioprine.⁵⁹ Patients with either newly diagnosed or relapsing disease were eligible for entry. Intravenous and a tapering course of oral steroids were used in the same manner in both groups. The primary outcome was remission. One hundred ninety-seven patients with either granulomatosis with polyangiitis (75% of patients) or microscopic polyangiitis (24%) were enrolled in the study. More patients treated with rituximab were in remission (64% versus 55%, $P = .21$), and this difference met the criterion for noninferiority ($P < .001$). Rituximab was more efficacious than cyclophosphamide in patients with relapsing disease at baseline.

Rituximab appears to be an effective alternative to cyclophosphamide for AAV and may be more effective in patients who have relapsing disease.

A randomized, controlled trial in which rituximab was compared with cyclophosphamide for ANCA-associated renal vasculitis has also been undertaken.⁶⁰ All patients received a standard glucocorticoid regimen with either four infusions of rituximab 375 mg/m² given at weekly intervals along with two intravenous cyclophosphamide pulses or intravenous cyclophosphamide given for 3 to 6 months followed by azathioprine. No significant difference was found in the proportion of patients in both groups who were in sustained remission at 12 months (76% versus 82%, rituximab versus control group, $P = .68$), and the number of early severe adverse events was similar in both groups.

SUMMARY

B-cell depletion therapy with rituximab has proved to be a promising area in terms of both clinical management and research on disease pathogenesis. In RA, the clinical benefits of such therapy have been important for the significant number of patients who have active progressive disease despite conventional and biologic DMARDs; evidence of its benefit in populations with earlier disease is now accruing. There are also increasing data on structural benefit. Questions remain regarding the most appropriate dose and the frequency of repeated treatments. The safety profile has been reassuring, with the treatment being suitable for some patients who may have a contraindication to anti-TNF therapy for safety reasons. Immunoglobulin levels—particularly IgG after several cycles—will need to be monitored carefully, although with regard to safety, there does not appear to be a need to monitor CD19 levels in routine clinical practice.

Rituximab is now approved by the FDA for treatment of AAV. In terms of toxicity, rituximab may also be a better alternative than cyclophosphamide for the treatment of other rheumatic diseases, including SLE, although careful surveillance for infection, especially PML, will be required. In SLE and Sjögren syndrome, confirmation of efficacy through well-designed clinical studies is still needed.

Cytokine neutralizers:
interleukin-1 inhibitors

■ CEM GABAY

- Interleukin-1 α (IL-1 α) and IL-1 β (also termed IL-1) are prototypic proinflammatory cytokines that activate effector cells by binding to IL-1 receptors.
- IL-1 is a very potent cytokine, the activities of which are tightly regulated by natural inhibitors such as IL-1 receptor antagonist (IL-1Ra), type 2 IL-1R, and soluble receptors. The balance between IL-1 and its natural inhibitor IL-1Ra has been shown to play a major role in the regulation of inflammatory responses.
- The production of mature and bioactive IL-1 β is regulated by two signals: signal 1 induces the production of pro-IL-1 β , a nonactive 31-kDa propeptide. Activation of the inflammasome, a cytosolic complex of proteins, leads to the activation of caspase-1, which causes processing of pro-IL-1 β into mature 17-kDa IL-1 β and its release outside the cells. In addition to caspase-1, other enzymes are also involved in the cleavage and maturation of IL-1 β .
- Exogenous microbial components and endogenous agents (monosodium urate and calcium dihydrate pyrophosphate crystals) can activate the NALP3 inflammasome. In addition, some mutations of NALP3 lead to spontaneous activation of the inflammasome and caspase-1 and overproduction of IL-1 β , which causes recurrent episodes of fever with inflammatory systemic manifestations.
- IL-1 inhibitors have been reported to be markedly effective in the management of systemic-onset juvenile idiopathic arthritis, adult-onset Still disease, crystal-induced arthritis, and periodic fever syndromes associated with either overproduction of IL-1 β or IL-1Ra deficiency.

INTERLEUKIN-1 FAMILY

Ligands and receptors

The IL-1 family includes three ligands: IL-1 α , IL-1 β , and IL-1 receptor antagonist (IL-1Ra).¹ IL-1 α and IL-1 β exert agonist activities and play critical roles in inflammatory responses. IL-1 α and IL-1 β are produced as 31-kDa propeptides. Pro-IL-1 β is biologically inactive and must be converted into mature IL-1 β to acquire the ability to bind to receptors and activate cells, whereas both pro-IL-1 α and mature IL-1 α are biologically active. However, the amino terminal region of pro-IL-1 α is also cleaved by Granzyme B, elastase, and calpain-1 proteases, which leads to marked enhancement of IL-1 α biologic activity.²

The IL-1 receptor family includes three receptors: type 1 IL-1 receptor (IL-1RI), type 2 IL-1 receptor (IL-1RII), and IL-1 receptor accessory protein (IL-1RAcP) (Fig. 61.1). Binding of IL-1 to IL-1RI leads to the recruitment of IL-1RAcP and cell signaling. IL-1RII has a short intracytoplasmic domain and is unable to transduce any intracellular signal and thus functions as a decoy receptor.³ Both membrane-bound and soluble IL-1RII can bind to IL-1 β and exert inhibitory functions (see Fig. 61.1).

IL-1Ra is structurally closely related to the other IL-1 ligands. IL-1Ra binds avidly to IL-1RI but fails to activate cells; it functions as a specific competitive inhibitor of IL-1. Several different isoforms of IL-1Ra are produced from the same gene, but the function of these intracellular isoforms remains unclear.⁴

Interleukin-1 plays a critical role in inflammation

In healthy human subjects, IL-1 β , contrary to other cytokines, is barely detectable in the bloodstream, thus suggesting that its circulating levels are below 10 pg/mL. Such low levels have to be maintained because of the tremendous potency of IL-1 β in inducing inflammatory responses.⁵ Experimental evidence indicates that IL-1 is involved in the development of arthritis.⁶ The importance of IL-1Ra as an endogenous modulator of inflammatory responses has been demonstrated by the use of gene knockout mice and more recently in humans genetically deficient in IL-1Ra. Breeding of IL-1Ra-deficient mice bred into the BALB/c background generates a spontaneous form of polyarthritis.⁷ The arthritis does not develop in germ-free conditions, and Toll-like receptor 4 (TLR4)-deficient mice have an attenuated form of arthritis, thus indicating the dependence of microbial flora. TLR4 signaling enhanced the disease by activating type 17 helper T cells (Th17) cells and increasing IL-17 production.⁸ Conditional knockout mice in which myeloid cell, including macrophages and dendritic cells, are selectively deficient in IL-1Ra exhibit an earlier onset and more severe form of collagen-induced arthritis with increased Th1 and Th17 responses.⁹ Finally, The occurrence of autoinflammatory manifestations in children deficient in IL-1Ra further supports the key regulatory role of this cytokine.^{10,11}

Regulation of interleukin-1 β maturation by the inflammasome

The mechanisms leading to the processing and release of mature IL-1 β have great relevance to many acute and chronic inflammatory diseases. It is currently hypothesized that two signals are required for release of IL-1 β from normal human monocytes. First, pro-IL-1 β synthesis is stimulated on binding of bacterial or endogenous components to the TLR. The second signal is NLR (NOD-like receptors)-induced IL-1 β processing and release through a caspase-1-dependent mechanism that is regulated by a multimeric cytosolic protein complex called the inflammasome. This complex contains caspase-1, the adapter protein PYCARD (also known as ASC), and a sensor protein belonging to the NLR family.¹² Activation of caspase 1 through the NALP3 inflammasome can be induced by stimulation with microbial molecules and endogenous molecules such as monosodium urate (MSU) and calcium pyrophosphate dihydrate (CPPD)¹³ (Fig. 61.2). Interestingly, activation of the NALP3/cryopyrin inflammasome has proved particularly important for many diseases characterized by overproduction of IL-1 β , such as some periodic fever syndromes and crystal-induced arthritis.¹⁴ In addition, pro-IL-1 β can also be cleaved in the extracellular environment by different inflammatory proteases to yield active IL-1 β .^{15,16}

THERAPEUTIC INHIBITORS OF INTERLEUKIN-1 IN RHEUMATIC DISEASES

Figure 61.3 depicts the different strategies that have been developed to inhibit the biologic effects of IL-1. The subsequent paragraphs describe the effect of IL-1 antagonists in the different rheumatic diseases (Table 61.1). Descriptions of the different IL-1 inhibitors is detailed in the section on rheumatoid arthritis (RA) because they were all tested or at least initially examined in experimental models of RA.

Rheumatoid arthritis

Anakinra (Kineret) interleukin-1 receptor antagonist

The results of a randomized double-blind controlled clinical trial showed that administration of anakinra was superior to placebo according to the

Fig. 61.1 Regulation of interleukin-1 (IL-1) activity by both membrane-bound and soluble forms of IL-1 receptors. (a) The biologic activities of IL-1, including membrane-bound pro-IL-1 α , mIL-1 α , and mIL-1 β , are mediated by binding to the cell surface receptor IL-1RI. Binding of IL-1 induces a conformational change in the extracellular component of IL-1RI that enables its interaction with IL-1RAcP, which is required for intracellular signaling. IL-1RII might act only as a decoy receptor either (b) on the cell surface or (c) as sIL-1RII in the extracellular environment after enzymatic cleavage of its extracellular domain. sIL-1RII contributes to IL-1 antagonism. IL-1RI (d) and IL-1RAcP (e) also exist as soluble forms that are produced by cleavage of the extracellular domain and alternative splicing, respectively. To date, the physiologic role of sIL-1RI is unclear. sIL-1RAcP can form an inactive complex with cell surface IL-1RI bound to IL-1 and (f) also increases the potency of sIL-1RII as an inhibitor of IL-1 action. IL-1RAcP, IL-1 receptor accessory protein; IL-1RI/II, IL-1 receptor type I/II; m, mature; s, soluble. (From Gabay C, Lamachia C, Palmer G. IL-1 pathways in inflammation and human diseases. *Nat Rev Rheumatol* 2010;6:232–41, copyright Nature Publishing group.)

Fig. 61.2 Mechanism of NLR family, pyrin domain-containing 3 (NLRP3) inflammasome complex formation. Under healthy cellular conditions, NLRP3 is autorepressed because of an internal interaction between the NACHT domain and LRRs. This autorepression is removed in the presence of pathogen-associated molecular patterns (PAMPs) from microorganisms or damage-associated molecular patterns (DAMPs) from endogenous danger signals. This results in exposure of the NACHT domain. In turn, NLRP3 oligomerizes and recruits apoptosis-associated specklike protein containing a CARD (ASC; also known as PYCARD) and pro-caspase-1, which triggers the activation of caspase-1 and maturation and secretion of proinflammatory cytokines such as interleukin-1 β (IL-1 β) and IL-18. Other cytoplasmic proteins, such as enzymes of the glycolytic pathway, are also substrates of active caspase-1. CARD, caspase-recruitment domain; LRRs, leucine-rich repeats; NACHT, NAIP, CIITA, HET-E and TP1; PYD, pyrin domain. (From Tschopp J, Schroder K. NLRP3 inflammasome activation: the convergence of multiple signalling pathways on ROS production? *Nat Rev Immunol* 2010;10:210–15, copyright Nature Publishing group.)

American College of Rheumatology (ACR) response criteria¹⁷ in preventing the progression of structural damage.¹⁸ In patients with active RA despite methotrexate (MTX) therapy, the combination of anakinra and MTX resulted in better ACR responses than MTX alone did.¹⁹ Safety data from a larger population indicate that anakinra in combination with different disease-modifying antirheumatic drugs (DMARDs) is safe, with a rate of serious infections slightly higher in the anakinra than in the placebo group (2.1% vs. 0.4%).²⁰

The combination of anakinra and etanercept did not show any advantage over etanercept alone but was associated with a significant increase in the

incidence of serious infections.²¹ Use of anakinra in patients who had a previous incomplete response to tumor necrosis factor- α (TNF- α) inhibitors did not show any advantage either.²²

Soluble interleukin-1 receptors

Administration of soluble IL-1RI (sIL-1RI) administered either by intra-articular or subcutaneous injection was devoid of significant effect in patients with RA.²³ Despite some interesting preclinical results, no data are available on the use of sIL-1RII or sIL-1RAcP in patients with RA or other diseases.

Fig. 61.3 (a) Anti-IL-1 β , IL-1 trap (rilonacept), and sIL-1RI can block extracellular IL-1 β . (b) Binding of active IL-1 to cell surface receptors can be inhibited by IL-1Ra and anti-IL-1RI antibodies. (c) Caspase-1 inhibitors can specifically inhibit the production of mature IL-1 β . IL, interleukin; IL-1RAcP, IL-1 receptor accessory protein; IL-1RI, IL-1 receptor type I; m, mature; s, soluble. (From Gabay C, Lamacchia C, Palmer G. IL-1 pathways in inflammation and human diseases. *Nat Rev Rheumatol* 2010;6:232–41, copyright Nature Publishing group.)

IL-1 trap (rilonacept, Arcalyst) is a fusion protein containing some of the extracellular binding motifs of IL-1RI and IL-1RAcP coupled to the Fc fraction of human immunoglobulin IgG1. IL-1 trap has a prolonged circulating half-life ranging from 128 to 214 hours that permits once-weekly subcutaneous dosing. Administration of a murine form of IL-1 trap almost completely blocked the development of mouse collagen-induced arthritis.²⁴ Despite some encouraging results observed in a phase 1 trial,²⁵ a subsequent multicenter, randomized, double-blind, placebo-controlled phase 2 clinical trial failed to show a significant effect.

Monoclonal antibodies

The safety and efficacy of ACZ885 (canakinumab, Ilaris), an intravenously or subcutaneously infused, fully human monoclonal antibody that neutralizes the bioactivity of human IL-1 β , were examined in a 6-week randomized, placebo-controlled, dose-escalating, clinical trial that included 32 patients with RA and an incomplete response to MTX. When compared with MTX alone, a higher number of patients achieved an ACR20 response with the combination of MTX and the highest dose of canakinumab (10 mg/kg), although the difference was not statistically significant.²⁶

The safety and efficacy of AMG-108, a fully human anti-IL-1RI monoclonal antibody was examined in 813 patients with RA who had an inadequate response to MTX in a 24-week randomized, double-blind, placebo-controlled, parallel-dosing clinical trial. After 24 weeks, 40.4% and 20.2% of patients receiving the highest dose of AMG-108 achieved ACR20 and ACR50 responses as compared with 29.1% and 8.4% in those treated with MTX alone ($P = .22$ and $P < .001$, respectively). No difference was detected between the different groups regarding the ARC70 response. No notable differences were seen in either the frequency or type of adverse events.²⁷

Inhibition of interleukin-1 β production

The efficacy and safety of pralnacasan, a synthetic orally administered caspase-1 inhibitor, were examined in a 12-week phase 2, placebo-controlled

multicenter study in patients with RA receiving concurrent DMARDs. The ACR20 response rate was not significantly higher in patients treated with pralnacasan than in the placebo group.²⁸

Despite positive results in animal models of arthritis, the results of clinical trials using anakinra and other IL-1 inhibitors have shown only modest therapeutic effects in patients with RA.

Ankylosing spondylitis

Anakinra treatment was moderately successful as assessed by clinical and magnetic resonance imaging (MRI) parameters in a 3-month open-label study that included nine patients with ankylosing spondylitis.²⁹ In another 24-week open-label clinical trial that included 20 patients with ankylosing spondylitis refractory to nonsteroidal antiinflammatory drugs, ASAS20, ASAS40, and ASAS70 responses were achieved by five, four, and two patients, respectively. No change was observed in the serum levels of C-reactive protein and MRI scores.³⁰

Psoriatic arthritis

An open-label, proof-of-concept, single-center study of 12 patients with psoriatic arthritis demonstrated significant clinical benefits. After 12 weeks, 50% met the response criteria for psoriatic arthritis, but anakinra had no effect on the cutaneous manifestations of psoriasis.³¹

Systemic lupus erythematosus

Anakinra led to some positive results in a few patients with lupus arthritis.³²

Osteoarthritis

The results of a randomized, double-blind, placebo-controlled study failed to show positive effects with a single intraarticular injection of anakinra for knee osteoarthritis (OA) at the 12-week evaluation.³³ This result is not unexpected in view of the short half-life of IL-1Ra. Of note, a positive trend ($P = .051$) on the Western Ontario–McMaster Universities Osteoarthritis Index (WOMAC) pain score was noted at day 4 in the 150-mg anakinra group versus placebo. In patients with an acute anterior cruciate ligament tear, administration of a single intraarticular injection of 150 mg anakinra led to a rapid and significant reduction in pain and improvement in function when compared with saline injection in a small 2-week randomized, double-blind clinical trial.³⁴ AMG-108, an antibody against IL-1RI, was administered subcutaneously or intravenously to patients with knee OA in a randomized double-blind placebo-controlled study. The AMG-108 group had statistically insignificant, but numerically greater improvement in pain than did the placebo group as shown by WOMAC pain scores (median change, -63.0 vs. -37.0 , respectively).³⁵

Further studies should investigate the rationale of IL-1 targeting for the signs and symptoms of OA and in the prevention of cartilage damage.

Crystal-induced arthritis

MSU and CPPD crystals are the agents responsible for gout and pseudogout, respectively. MSU and CPPD crystals can stimulate the NALP3 inflammasome and thus lead to pro-IL-1 β processing and secretion of IL-1 β .³⁶ More recently, it has also been shown that MSU crystals induce the release of IL-1 α .³⁷ The basic calcium crystals that are associated with severe OA and periarticular inflammation can also stimulate the release of IL-1 β by cultured macrophages through activation of the NALP3 inflammasome.³⁸

In a multicenter, randomized, double-blind, dose-escalating controlled clinical trial, one subcutaneous injection of canakinumab, 150 mg, provided more rapid relief of pain in patients with acute gout and significantly reduced the risk for subsequent gouty flares when compared with one intramuscular injection of triamcinolone acetonide, 40 mg.³⁹ These positive results were confirmed in two subsequent multicenter, randomized controlled trials.⁴⁰ Canakinumab at a dosage of 50 mg or higher was superior to colchicine, 0.5 mg daily, in the prevention of gouty flares following the initiation of allopurinol.⁴¹ The use of rilonacept (IL-1 trap) in a multicenter clinical trial on acute gout has provided interesting preliminary results.⁴² Two subsequent clinical trials showed that rilonacept significantly reduces gout attacks following the initiation of allopurinol.^{43,44} Anakinra is efficacious in the treatment of acute pseudogout refractory to or intolerant of usual therapy,⁴⁵ as well as in the prevention of acute attacks.⁴⁶

TABLE 61.1

Interleukin-1 inhibitors in the treatment of rheumatic diseases

Disease	Biologic agent	Type of study	Primary outcome	Results
RA	Anakinra vs. placebo	RCT	ACR20 response criteria	Significant improvement ¹⁷
RA	Anakinra vs. placebo	RCT	Genant and Larsen scores	Limits structural damage ¹⁸
RA	Anakinra + MTX vs. MTX	RCT	ACR20 response criteria	Significant improvement ¹⁹

ACR, American College of Rheumatology; AOSD, adult-onset Still disease; AS, ankylosing spondylitis; ASAS, Assessment of SpondyloArthritis International Society; CAPS, cryopyrin-associated periodic syndromes; FCAS, familial cold autoinflammatory syndrome; HAQ-DI, health assessment quality-disability index; MWS, Muckle-Wells syndrome; OA, osteoarthritis; PsA, psoriatic arthritis; RA, rheumatoid arthritis; RCT, randomized placebo-controlled clinical trial; SOJIA, systemic-onset juvenile idiopathic arthritis; WOMAC, Western Ontario-McMaster Universities Osteoarthritis Index.

Systemic-onset juvenile idiopathic arthritis and adult Still disease

Treatment with anakinra was reported to be dramatically successful in nine patients with refractory systemic-onset juvenile idiopathic arthritis (SOJIA).⁴⁷ A recent observational study indicated that only 40% of patients with SOJIA had a marked and persistent response to anakinra that led to a reduction or discontinuation of co-medications, including corticosteroids. A higher neutrophil count and lower number of active joints were associated with a good response to anakinra.⁴⁸ Anakinra has been reported to be effective for adult Still disease, with responses that could be even better than those for SOJIA.⁴⁹ Currently in phase 3 clinical development, canakinumab was recently granted E.U. and U.S. orphan drug status for this condition, as well as for cryopyrin-associated periodic syndromes (see the next section). Early clinical trials have shown that administration of canakinumab every 2 weeks is safe and effective and thus offers a considerable advantage over anakinra.

Interleukin-1 inhibition for periodic fever syndromes

The term “cryopyrinopathies” or “cryopyrin-associated periodic syndromes” (CAPSs) was coined for a group of inherited disorders that includes

neonatal-onset multisystem inflammatory disease (NOMID; also known as chronic infantile neurologic, cutaneous, articular syndrome [CINCA]), Muckle-Wells syndrome (MWS), and familial cold autoinflammatory syndrome (FACS), a condition characterized by recurrent episodes of fever and inflammatory responses in multiple organs. All these diseases have been associated with mutations in the *CIAS1* or *NLRP3* gene, which encodes for cryopyrin or NALP3. Administration of anakinra to patients with MWS and FACS resulted in the cessation of symptoms within hours of the first injection along with a concomitant decrease in serum amyloid A, an acute-phase protein; normal levels were reached after 3 days of treatment.⁵⁰ Significant improvement in NOMID/CINCA with anakinra has also been reported. Rilonacept has likewise been tested with success in patients with FACS.⁵¹ These favorable results were confirmed by two consecutive randomized, placebo-controlled phase 3 clinical trials that included 47 adults with CAPS. The treatment was well tolerated except for injection site reactions and upper respiratory tract infections.⁵² These results led to the approval of rilonacept by the Food and Drug Administration for the treatment of FACS and MWS in adults or children 12 years or older. Canakinumab was administered in an open-label clinical trial as a single subcutaneous injection, with redosing on relapse in seven patients with CAPS. All patients achieved a complete response within 24 hours following canakinumab administration according to physician assessments. The response was sustained for a median time of 49 days.⁵³ The 2-year results of a multicenter, open-label

study conducted in 161 pediatric and adult patients with CAPS showed that among 109 patients who were naive to canakinumab, 85 (78%) achieved a complete response. Adverse events included infections and injection site reactions, which were reported in a minority of patients (8%). Immune responses to vaccination were normal.⁵⁴

Other autoinflammatory disorders

Several other disorders featuring periodic fever, joint symptoms, and systemic manifestations are also classified as “autoinflammatory diseases.”⁵⁵ The spectacular effect of treatment of CAPS with anakinra inspired several clinical trials in patients with other autoinflammatory syndromes. Regression of symptoms after anakinra treatment was observed in patients with pyogenic arthritis and pyoderma gangrenosum acne syndrome.⁵⁶ Anakinra and canakinumab have been used with success in patients with severe familial Mediterranean fever who did not respond to or were intolerant of colchicine.⁵⁷ Interestingly, anakinra also had a beneficial effect on TNF receptor-associated periodic syndrome (TRAPS), an inherited disease caused by a mutation modifying the control of TNF signaling. In addition to systemic autoinflammatory diseases associated with mutations in proteins related to the inflammasome, IL-1 inhibitors also displayed efficacy in patients with Schnitzler syndrome and neutrophilic skin disorders such as Sweets syndrome, pyoderma gangrenosum, and hidradenitis suppurativa. Finally,

gevokizumab, a humanized monoclonal antibody against IL-1 β , was efficacious in some patients with the refractory uveitis of Behçet syndrome.⁵⁸

General comment on available interleukin-1 inhibitors

Use of IL-1 inhibitors has been particularly successful in conditions associated with acute inflammatory flares, the presence of neutrophilic infiltrates, and also sometimes blood neutrophilia. Unfortunately, because blood levels of IL-1 are only marginally elevated or most often undetectable, they are of no value in predicting response to IL-1 inhibitors. In general, the response to IL-1 inhibitors is very rapid and occurs within days and sometimes a few hours after the initiation of therapy. Anakinra is used in general at a dosage of 100 mg via daily subcutaneous injections (children: 1 to 2 mg/kg). Canakinumab is administered subcutaneously at a dosage of 150 mg every 8 weeks (children: 2 mg/kg). Rilonacept is given as a loading dose of 320 mg followed by weekly subcutaneous injections of 160 mg (children: 4.4 mg/kg followed by 2.2 mg/kg, up to 320 and 160 mg, respectively). In patients with severe organ manifestations or residual inflammation, a higher dosage of IL-1 inhibitors may be required to obtain complete remission. IL-1 inhibitors are generally well tolerated, but the rate of infections, predominantly upper airway infections, and injection site reactions is increased. Combination with TNF antagonists should be avoided.

Interleukin-6 inhibition

■ EDWARD KEYSTONE ■ MOHAMMED A. OMAIR

- Interleukin-6 (IL-6) is a multifunctional cytokine that plays a critical role in the pathogenesis of rheumatoid arthritis.
- Tocilizumab, a humanized monoclonal antibody directed against the IL-6 receptor, leads to significant improvement in clinical disease activity, functional state, and well-being, as well as inhibition of structural damage.
- Tocilizumab appears to have comparable efficacy when taken in combination with methotrexate and as monotherapy.
- Tocilizumab has demonstrated clinical benefit in patients with juvenile idiopathic arthritis, adult-onset Still disease, Takayasu disease, and giant cell arteritis.
- Serious adverse effects such as infection, colonic perforation, and malignancy are rare. More common nonserious adverse events include elevated liver transaminases, leukopenia, and hyperlipidemia.

INTERLEUKIN-6 AND INTERLEUKIN-6 RECEPTOR

Interleukin-6 (IL-6) is a member of the IL-6 family, which consists of polypeptide cytokines with a four- α -helix structure and a molecular mass of 21 to 28 kDa. Formerly named B-cell stimulatory factor 2, IL-6 is multifunctional cytokine produced by T cells, B cells, monocytes, fibroblasts, keratinocytes, endothelial cells, mesangial cells, and several tumor cells.¹ IL-6 receptor (IL-6R) belongs to the cytokine receptor class I family and has two components: an 80-kDa IL-6 binding protein (α chain) and a 130-kDa signal transducer known as glycoprotein 130 (gp130) (β chain).² IL-6R exists in two forms: a soluble IL-6 receptor (sIL-6R) and a membrane-bound (or transmembrane) IL-6 receptor (mIL-6R). IL-6 trans-signaling occurs through sIL-6R, which activates cells that express gp130, whereas classic signaling is limited to cells that express mIL-6R.³ Binding of IL-6 to IL-6R leads to homodimerization or heterodimerization of the gp130 subunit, which results in formation of the high-affinity IL-6/IL-6R/gp130 complex. This complex activates the Janus tyrosine kinase/signal transducer and activator of transcription (STAT) pathway. STAT and CCAAT enhancer binding proteins (C/EBPs) bind to DNA and regulate the expression of IL-6-type responsive genes. IL-6 has a wide range of biologic activities, including immune regulation, hematopoiesis, inflammation, and oncogenesis (Table 62.1).

TOCILIZUMAB**Mechanism of action**

Tocilizumab is a genetically engineered monoclonal antibody humanized from a mouse antihuman IL-6R antibody. Tocilizumab recognizes the IL-6 binding site of the human IL-6R and inhibits IL-6 signaling through competitive blockade of the IL-6 binding site. It can bind to both sIL-6R and mIL-6R, thus inhibiting both classic signaling and trans-signaling in cells that express mIL-6R or gp130, respectively (Fig. 62.1). Tocilizumab recognizes IL-6R and inhibits binding of IL-6 to its receptors while not blocking the signaling of other IL-6 family cytokines. It blocks the action of IL-6 without increasing its half-life. Despite being an IgG1 antibody, in humans tocilizumab causes no antibody-dependent cellular cytotoxicity or complement-dependent cytotoxicity in cells that express IL-6R.

Pharmacokinetics

The half-life of tocilizumab in patients with rheumatoid arthritis (RA) depends on its concentration; the concentration-dependent apparent half-life is up to 11 days for 4 mg/kg and up to 13 days for 8 mg/kg administered every 4 weeks in patients with RA at a steady stage. The half-life of tocilizumab in children with systemic juvenile idiopathic arthritis (JIA) at steady state ranged from 18.4 to 22.7 days at 8 mg/kg in those with a body weight of 30 kg or greater and from 19.2 to 23 days at 12 mg/kg in those with a body weight lower than 30 kg.

Recommended dose and dose adjustment

Tocilizumab should be given in combination with methotrexate (MTX) or other disease-modifying antirheumatic drugs (DMARDs) or may also be given as monotherapy in patients intolerant of MTX or in whom MTX is not appropriate. The recommended starting dose in North America for adult patients is 4 mg/kg given once every 4 weeks as an intravenous infusion over a 1-hour period, followed by an increase to 8 mg/kg, depending on clinical response. For patients in Europe and Japan the starting dose is 8 mg/kg. It is recommended for patients who have had an inadequate response to one or more DMARDs or tumor necrosis factor (TNF) antagonists. In individuals whose body weight is greater than 100 kg, doses exceeding 800 mg per infusion are not recommended. Dose adjustments should be considered for the management of dose-related laboratory changes, including elevated liver enzymes (alanine aminotransferase [ALT] and aspartate aminotransferase [AST]), neutropenia, and thrombocytopenia.

Clinical trial results

The efficacy of combination therapy with tocilizumab in patients with moderate to severe disease has been demonstrated in several multicenter, double-blind, randomized controlled trials (DBRCTs) with MTX alone and with other conventional DMARDs.

One of the early studies was a 24-week, phase 2 DBRCT of 1220 patients receiving 8 mg/kg tocilizumab in combination with conventional DMARDs versus DMARDs alone.⁴ The American College of Rheumatology 20% improvement (ACR20) response of the group receiving tocilizumab plus DMARDs at 24 weeks was significantly greater than the response in the control group (61% versus 25%). ACR50/70 responses, 28-joint disease activity score (DAS28), DAS28 remission rates, European League Against Rheumatism (EULAR) responses, and changes in C-reactive protein (CRP) and hemoglobin demonstrated superiority of tocilizumab plus DMARDs over DMARDs alone. Another 24-week DBRCT confirmed these findings in 619 patients receiving conventional DMARDs with 8 mg/kg tocilizumab.⁵

In a 623-patient, 24-week phase 3 DBRCT of patients with an inadequate response to MTX, tocilizumab was examined at 4- and 8-mg/kg doses versus placebo plus MTX.⁶ At 24 weeks, ACR20 responses in the 8-mg/kg group (59%) and the 4-mg/kg group (48%) were superior to those in the group that received placebo plus MTX (26%). The time until maximum effect was 24 weeks, as demonstrated by a plateau of the mean DAS28 response. In this study the mean CRP level did not normalize in the 4-mg/kg group by 24 weeks, whereas it normalized in the 8-mg/kg group by 2 weeks. In another phase 3 study, 4- and 8-mg/kg doses of tocilizumab plus MTX were evaluated in a 2-year study of 1196 patients to examine structural damage.⁷ At 1 year significantly less progression in the Genant-modified Sharp score (G-SS) was seen in the 4-mg/kg (0.34 G-SS units) and 8-mg/kg (0.29 G-SS units) tocilizumab-plus-MTX groups than in the MTX-plus-placebo group (1.13 G-SS units). Superiority of tocilizumab was also confirmed for ACR20, ACR50, and ACR70 responses; the health assessment disability index; and DAS28 remission relative to the MTX-plus-placebo group (Fig. 62.2).

Tocilizumab also demonstrated dissociation between its clinical and radiographic outcomes, similar to what has been described with tumor necrosis factor inhibitors (TNFIs).

Tocilizumab in combination with MTX was also evaluated in patients refractory to TNFIs. In a 24-week, phase 3 study of 499 patients, the efficacy of tocilizumab was examined at doses of 4 and 8 mg/kg plus MTX versus placebo plus MTX.⁸ At 24 weeks, ACR20 responses were achieved in 50.0%, 30.4%, and 10.1% of patients in the 8- and 4-mg/kg tocilizumab and control groups, respectively. Patients responded regardless of the most recent TNFI or number of TNFI failures. To study whether patients with an inadequate response to 4 mg/kg would benefit from dose escalation to 8 mg/kg, a

post-hoc pooled analysis of clinical trial data was performed in those who responded inadequately to DMARD and TNFI; significant improvement in DAS28 occurred with escalation of tocilizumab from 4 to 8 mg/kg at 16 weeks.⁹ Slowing of radiographic progression was also demonstrated with dose escalation. These data suggest that in inadequate responders to DMARD and TNFI who do not achieve an adequate response to 4 mg/kg tocilizumab, escalation to the 8-mg/kg dose should be carried out.

It has been suggested that approximately a third of rheumatoid patients treated with biologics receive them as monotherapy without MTX. Tocilizumab monotherapy was found to be similar in efficacy to tocilizumab given in combination with conventional DMARDs, including MTX, in several studies. In one of the first DBRCTs, tocilizumab was evaluated in 359 patients at doses of 2, 4, and 8 mg/kg either as monotherapy or in combination with MTX; MTX plus placebo was used as control.¹⁰ An ACR20 response was achieved by 63% and 74% of patients receiving 4- and 8-mg/kg doses of tocilizumab with MTX, respectively, as compared with 61% and 63% of patients receiving monotherapy, respectively, and 41% of patients receiving placebo plus MTX. A dose-related reduction in DAS28 starting at week 2 was observed in all patients except those receiving 2 mg/kg tocilizumab monotherapy. The kinetics of the DAS28 response was similar with both the 4- and 8-mg/kg doses. The CRP level normalized in the first 2 weeks of therapy except in those receiving 2 mg/kg and those receiving 4 mg/kg as monotherapy. Patients treated with 4 mg/kg had a sawtooth pattern with a decrease in CRP 2 weeks after dosing and an increase before the next infusion. The 8-mg/kg dose produced a more sustained decrease. Similar results were achieved with tocilizumab monotherapy (8 mg/kg) in a 2-year open-label DMARD controlled trial of 306 patients; tocilizumab monotherapy reduced radiographic progression comparable to the DMARD combination group.¹¹ In a 24-week, double-blind study of 673 patients in whom MTX or biologic agents had not failed,¹² patients were randomized to either 8 mg/kg tocilizumab or MTX monotherapy (Fig. 62.3). Tocilizumab monotherapy was more effective than MTX, with a higher ACR20 response rate (69.9% versus 52.2%) and DAS28 score (33.6% versus 12.1%), respectively. In another study, 556 patients were randomized in a 2-year DBRCT to tocilizumab (8 mg/kg) monotherapy or to continue with tocilizumab in combination with MTX.¹³ At 24 weeks the DAS28–erythrocyte sedimentation rate (ESR) for tocilizumab monotherapy was not statistically different from that for the combination of tocilizumab and MTX (40.4% versus 34.8%). Even though the ACR responses were also comparable in the tocilizumab monotherapy and tocilizumab-plus-MTX groups, significantly more patients in the combination group achieved a DAS28 low disease state than did those in the monotherapy group (61.7% versus 51.4%). No difference in radiographic progression was noted in the two groups.

Because clinical trials may not always reflect clinical practice, several 24-week, multicenter open-label phase 3b studies were performed to examine tocilizumab in a setting closer to real-life medical care. In a study

TABLE 62.1
Effect of interleukin-6 on different cell lines during the immune response

Cell type	Effect
T cells	Proliferation and differentiation of T cells, including cytotoxic T lymphocytes and Th17 cells Augmentation of NK activity Inhibition of regulatory T cells
B cells	Increase immunoglobulin production (including rheumatoid factor)
Macrophages	Differentiation
Neutrophils	Increase demargination
Megakaryocytes	Enhancement of megakaryocytopoiesis Maturation of megakaryocytes
Hepatocytes	Stimulation of hepatocytes to produce acute-phase proteins such as CRP, fibrinogen, α_1 -antitrypsin, and serum amyloid A Stimulation of hepcidin Suppression of albumin production
Synoviocytes	Proliferation and pannus formation (inhibition of TNF- α -induced synovial growth) Production of VEGF
Osteodasts	Formation and differentiation leading to bone resorption
Endothelial cells	IL-8 production Activation of chemotaxis Production of adhesion molecules

CRP, C-reactive protein; NK, natural killer; Th17, type 17 helper T cell; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

Fig. 62.1 Both the soluble (sIL-6R) and membrane-bound (mIL-6R) forms of the IL-6 receptor are inhibited by tocilizumab. gp130, glycoprotein 130. (With permission of Roche Global, Basel, Switzerland.)

Fig. 62.2 Changes in radiologic scores in patients taking 4 mg/kg tocilizumab (TCZ) plus methotrexate (MTX), 8 mg/kg tocilizumab plus MTX, or placebo (PBO) plus MTX. (a) Mean change from baseline in the total Genant-modified Sharp score, erosion score, and joint space narrowing score at week 52 in the intent-to-treat (ITT) population. Data collected after withdrawal or while patients were receiving rescue therapy were excluded. Numbers at the top of the bars are the values represented by the bars. (b) Cumulative distribution of change from baseline in the total Genant-modified Sharp score to week 52 in the ITT population. Data collected after withdrawal or while patients were receiving rescue therapy were excluded. (c) Change in the total Genant-modified Sharp score over time in the ITT population (as-observed analysis [postwithdrawal, postrescue data excluded]). * $p < .0001$ versus placebo plus MTX; † $p < .05$ versus placebo plus MTX (the test failed, however, after a break in the hierarchic chain of the algorithm; therefore, statistical significance is not claimed); ‡ $p < .01$ versus placebo plus MTX. (From Kremer JM, Blanco R, Brzosko M, et al. Tocilizumab inhibits structural joint damage in rheumatoid arthritis patients with inadequate responses to methotrexate: results from the double-blind treatment phase of a randomized placebo-controlled trial of tocilizumab safety and prevention of structural joint damage at one year. *Arthritis Rheum* 2011;63:609-21.)

of 286 patients, tocilizumab at a dose of 8 mg/kg resulted in major improvements in patient-reported outcomes and DAS28 response.¹⁴ In another open-label study of 1681 patients, ACR responses, DAS28, clinical disease activity index (CDAI), and simple disease activity index (SDAI) remission with tocilizumab monotherapy (8 mg/kg) were found to be comparable to those achieved with tocilizumab-DMARD combination therapy at 24 weeks in inadequate responders to both DMARD and TNF.¹⁵ In an open-label, randomized U.S. study of previous inadequate responders to anti-TNF,^{16,17} patients treated with monotherapy or combination conventional DMARD therapy were randomized to 4 or 8 mg/kg tocilizumab and their current DMARDs, whereas those who previously received TNFI monotherapy were switched to 8 mg/kg tocilizumab alone. The efficacy of 8 mg/kg tocilizumab monotherapy and combination tocilizumab and conventional therapy was found to be equivalent in inadequate responders to TNFI.

Tocilizumab monotherapy (8 mg/kg) versus adalimumab 40 mg every 2 weeks was studied in a 24-week DBRCT.¹⁸ Three hundred twenty-six patients with a disease duration of 6.3 to 7.3 years who were intolerant of MTX or for whom continued treatment with MTX was inappropriate were enrolled in this study. The mean change in DAS28 at 24 weeks was significantly greater with tocilizumab (−3.3) than with adalimumab (−1.8). Tocilizumab demonstrated superiority over adalimumab with respect to DAS28 remission rates (39.9 versus 10.5), DAS28 low-disease state rates (51.5 versus 19.8), and CDAI remission rates (17.2 versus 9.3). The incidence of adverse events was similar between groups, although elevations in transaminases and low-density lipoprotein (LDL) and reductions in neutrophils were higher in the tocilizumab group.

In all the tocilizumab trials, DAS28 remission rates were higher with tocilizumab than the historical responses with other biologics despite similar remission rates as measured by the more stringent SDAI and CDAI criteria. The greater effect of tocilizumab through IL-6 inhibition than other biologics in reducing ESR and CRP coupled with high weighting of the acute-phase reactants in DAS28 accounts for the disparity.

Long-term effects

The long-term effects of tocilizumab were reported in 2904 inadequate responders to DMARD and 616 patients who had never been exposed to or failed MTX therapy (NE/NF).¹⁹ After a median of 3.55 years (range, 0 to 5.1 years), 30.0% of inadequate responders to DMARDs and 26.4% of NE/NF had withdrawn. Of patients who were still taking tocilizumab at week 216 in the group of inadequate responders to DMARDs, 73% achieved a DAS28 low-disease state and 53% achieved a DAS28 remission.

Safety

The most frequently reported adverse events in the clinical trial population treated with tocilizumab were upper respiratory infections, nasopharyngitis, headaches, increased transaminase levels, and upper abdominal pain.

Infections

In an integrated safety review of the core controlled clinical trial population (N = 4199), the most common serious adverse events reported (>0.3 per 100 patient-years [PY]) were pneumonia, cellulitis, urinary tract infection, gastroenteritis, sepsis, and herpes zoster.²⁰ Rates of serious infection in this controlled population were 3.5 per 100 PY for the control group, 3.5 per 100 PY for the 4-mg/kg tocilizumab group, and 4.9 per 100 PY for the 8-mg/kg group. In patients included in the controlled and extension phases of these trials, serious opportunistic infections were seen in 14 patients and included tuberculosis (TB), candidiasis (systemic, esophageal, gastrointestinal, osteomyelitis), fungal infections, and *Mycobacterium avium*, *Pneumocystis jiroveci*, and cryptococcal pneumonia. All opportunistic infections except one occurred in the 8-mg/kg tocilizumab group. Patients were screened for latent TB in the trials according to local country guidelines, and patients with pulmonary TB were from highly endemic areas. The rate of serious infection with tocilizumab therapy was comparable to that reported with other biologics used for RA. An update on long-term safety (median disease duration of 3.6 years) revealed stable rates of serious adverse events and serious infections with continued long-term tocilizumab exposure.²¹ With regard to viral infections, cases of herpes zoster were observed. No cases of hepatitis B occurred, but patients who screened positive were excluded. Data are not available on vaccination responses in patients receiving tocilizumab.

Gastrointestinal perforation

In the integrated safety analysis, 18 gastrointestinal perforations (including diverticular perforation in 11 patients) were identified,²⁰ the majority of which occurred in the colon. A systematic review of diverticular disease in

Fig. 62.3 (a) Proportion of patients achieving American College of Rheumatology 20% improvement (ACR20), ACR50, and ACR70 responses at week 24 (intent-to-treat [ITT] population). The results demonstrate that treatment with tocilizumab is significantly better than treatment with methotrexate (* $p < .001$; ** $p < .002$; *** $p < .001$). (b) Proportion of methotrexate-naïve patients achieving ACR20, ACR50, and ACR70 responses at week 24 (ITT population). *Weighted difference between groups = 0.15 (95% confidence interval [CI], 0.05 to 0.25), $p < .004$; **weighted difference between groups = 0.14 (95% CI 0.03 to 0.24), $p = .01$; ***weighted difference between groups = 0.15 (95% CI, 0.04 to 0.25), $P = .005$. (c) Time course for achievement of ACR20, ACR50, and ACR70 responses during 24 weeks of treatment with tocilizumab or methotrexate (ITT population). (d) Proportion of patients in clinical remission (DAS28 <2.6) and proportion of patients with a good or moderate European League Against Rheumatism (EULAR) response at week 24 (ITT population). (e) C-reactive protein (CRP) levels at each postbaseline visit during the 24-week study (ITT population). (f) Hemoglobin levels at each postbaseline visit during the 24-week study (safety population). LLN, lower limit of normal; ULN, upper limit of normal. (From Jones G, Sebba A, Gu J, et al. Comparison of tocilizumab monotherapy versus methotrexate monotherapy in patients with moderate to severe rheumatoid arthritis: the AMBITION study. *Ann Rheum Dis* 2010;69:88-96.)

RA did not reveal evidence of diverticular perforation in DMARD-treated patients.²² In the 18 cases of lower gastrointestinal perforation with tocilizumab just noted, the rate of 1.9 events per 1000 PY was lower than that reported with corticosteroids (3.9/1000 PY), but slightly higher than the rate with TNFIs (1.3/1000 PY) in the United Health Care database. The majority of these patients were also concurrently receiving nonsteroidal antiinflammatory drugs and long-term glucocorticoids. Oral corticosteroid use and preexisting diverticulitis were independently associated with a higher risk for perforation with tocilizumab. A new onset of abdominal symptoms in tocilizumab-treated patients should therefore prompt evaluation for gastrointestinal perforation.

Malignancies

The overall rate of malignancy, including nonmelanoma skin cancer (NMSC), was 1.1 per 100 PY, with rates of 0.3 per 100 PY for NMSC alone, 0.7 per 100 PY for solid cancer, 0.1 per 100 PY for hematologic/lymphatic malignancy, and none for other cancers.²¹ The overall rate of malignancy in these subsets of malignancies remained stable with continued tocilizumab therapy. The standardized incidence rate of 1.1 for the malignancies occurring at the U.S. sites was comparable to the U.S. Surveillance, Epidemiology, and End Results database. The overall malignancy rate during the placebo-controlled period of the clinical trials was similar to that in the control population²⁰ (Table 62.2).

Cardiovascular events

Few cardiovascular events occurred during the placebo-controlled period, and rates with tocilizumab were similar to those in the control population.

In a recent long-term update of the all exposed population, the overall rate of myocardial infarction was 0.3 per 100 PY and that for stroke was 0.2 per 100 PY, both of which remained stable over time. These rates did not exceed those expected in the rheumatoid population (myocardial infarction, 0.4 to 0.8/100 PY; stroke, 0.5 to 0.9/100 PY).

Infusion reactions

The rate of infusion reactions reported with tocilizumab during or within 24 hours of infusion (8% with 4 mg/kg and 7% with 8 mg/kg) was only slightly higher than that reported in the DMARD plus placebo control group (5%). The development of hypertension and hypotension was similar with both doses (1%) and was the most frequently reported event during the infusion. The most frequently reported events within 24 hours of completing an infusion were headache and skin reactions (both 1% for both doses).^{22a}

In a 2011 consolidated safety reporting of five core phase III studies, eight patients experienced clinically significant anaphylactic reactions, seven of which occurred during the first four infusions of tocilizumab. Five events were reported in the 4 mg/kg group, and three events were reported in the 8 mg/kg group. All eight patients with anaphylaxis were required to discontinue tocilizumab treatment.^{22b} Postmarketing reports of anaphylaxis, including events with a fatal outcome, have been reported.

Hematology

A dose-related decrease in the mean neutrophil count has been observed in the first 2 weeks after drug initiation. The neutrophil count increased but did not normalize by 4 weeks and remained stable for up to 24 weeks in the clinical studies. Neutrophil counts between 500 and 1000/mm³ were

TABLE 62.2
Serious adverse events reported at a rate of 0.3 per 100 patient-years or greater in any group (all-control population)

	All-control population (N = 4199): rate per 100 patient-years (number of events)		
	Control (n = 1555)	Tocilizumab 4 mg/kg + DMARDs (n = 774)	Tocilizumab 8 mg/kg + DMARDs (n = 1870)

DMARD, disease modifying antirheumatic drug; PY, patient-years.
 From Schiff MH, Kremer JM, Jhreis A, et al. Integrated safety in tocilizumab clinical trials. *Arthritis Res Ther* 2011;13(5):R141.

observed in 4.1% of the patients. Neutrophil counts lower than 500/mm³ were observed in 0.6% of patients, almost all of whom normalized with discontinuation of tocilizumab. The patients continuing on tocilizumab demonstrated improvement in their neutropenia—the majority returning to the normal range. No patient with a neutrophil count lower than 500/mm³ experienced a temporally associated serious infection, but by protocol, use of the drug was stopped. A decrease in the mean platelet count was observed at 2 weeks with tocilizumab treatment, but the majority of platelet counts remained in the normal range. Thrombocytopenia (<50,000/mm³) was observed in 0.8% of patients. Neutrophils and platelets should be monitored every 4 to 8 weeks. Tocilizumab therapy should be interrupted in patients with neutrophil counts between 500 and 1000/mm³ and restarted when the neutrophil count reaches 1000/mm³. It should be discontinued for counts below 500/mm³. Tocilizumab should be interrupted when the platelet count is between 50,000 and 100,000/mm³ and restarted at 4 mg/kg when the platelet count is higher than 100,000/mm³. For counts lower than 50,000, tocilizumab should be discontinued.

It is notable that an increase of approximately 1.0 g/dL in mean hemoglobin level was seen by 6 weeks, with the greatest improvement occurring in patients whose baseline hemoglobin was below the lower limit of normal.

Transaminase elevations

At least a single elevation in ALT of greater than one to three times the upper limit of normal (ULN) was observed in the first 6 months of treatment in 32% of patients treated with MTX monotherapy, in 19.1% of patients treated with non-MTX DMARDs, and in 33.8% of patients treated with 8 mg/kg tocilizumab. In patients treated with combination therapy, similar elevations in ALT levels were observed at least once in 42.8% and 45.9% of patients treated with 4 and 8 mg/kg tocilizumab plus DMARDs, respectively. Most ALT/AST elevations were transient and returned to normal without

dose adjustment or discontinuation of therapy. Elevated transaminases were not associated with clinically significant hepatitis, reduced liver function, or serious adverse effects. Because tocilizumab may unmask Gilbert syndrome, in patients in whom elevated bilirubin develops, measurement of indirect bilirubin should be done to confirm this diagnosis. This does not require stopping therapy.²¹

Dose adjustments are made for the management of elevated liver enzymes. For laboratory values higher than one to three times the ULN, the dose of the concomitant DMARD should be modified if appropriate. For persistent increases in this range, the dose of tocilizumab should be reduced to 4 mg/kg or its use interrupted until ALT/AST values have normalized. For ALT/AST higher than three to five times the ULN, tocilizumab dosing should be interrupted until lower than three times the ULN and the recommendations above followed for greater than one to three times the ULN.

Lipids

Total cholesterol, LDL, high-density lipoprotein, and apolipoproteins A-I and B were increased with tocilizumab in combination with DMARDs or as monotherapy at the first assessment at 6 weeks and remained elevated without a further increase for the duration of the treatment.²⁰ Similar elevations were seen in both the 4- and 8-mg/kg tocilizumab groups. In patients not receiving lipid-lowering agents, LDL cholesterol increased from less than 130 mg/dL at baseline to 130 mg/dL or higher in 14.2% of patients in the control group, in 25.1% in the 4-mg/kg tocilizumab group, and in 33.2% in the 8-mg/kg tocilizumab group. The significance of the lipid elevations with tocilizumab in patients with RA remains to be determined. Lipid parameters should be monitored every 4 to 8 weeks initially for 6 months and then every 6 months thereafter, and many rheumatologists initiate lipid-lowering therapies (i.e., statins) in patients in whom LDL higher than 130 mg/dL develops.

Indications and uses

Worldwide, tocilizumab is now approved for reduction of the signs and symptoms in adult patients with established moderate to severe RA who have demonstrated an inadequate response to one or more DMARD. It can be given as monotherapy or in combination with DMARDs. In the United States the recommended starting dose is 4 mg/kg intravenously every 4 weeks followed by an increase to 8 mg/kg based on clinical response, whereas in Europe and Japan the starting dose is 8 mg/kg with dose reduction for adverse events. Tocilizumab is administered over a 1-hour period. Doses higher than 800 mg per infusion are not recommended in adults with RA.

Tocilizumab is also indicated for patients 2 years and older with systemic JIA. The recommended dose for juvenile patients is 12 mg/kg every 2 weeks in those less than 30 kg weight and 8 mg/kg in those at or above 30 kg.

Use in specific populations

Pregnancy and nursing

Data on pregnancy outcomes in women exposed to tocilizumab during pregnancy are limited.²³ Evaluation in mice demonstrated no harm to offspring during the predevelopment and postdevelopment phases. There is no information on whether tocilizumab is excreted in human milk or absorbed systemically after ingestion. The decision whether to discontinue nursing or tocilizumab must be balanced by the importance of the drug for the mother.

Use in the elderly

Of the 2644 patients receiving tocilizumab in clinical studies, 435 were 65 years or older, including 50 patients 75 years or older, and the frequency of serious infections was higher in such patients than in those younger than 65. This is not unexpected because the elderly population has a higher incidence of infection in general.

Hepatic or renal impairment

The safety of tocilizumab has not been evaluated in patients with hepatic impairment. According to current prescribing guidelines, tocilizumab should not be initiated in patients with an ALT level higher than 1.5 times normal. No dose adjustment is required in patients with mild renal impairment. Tocilizumab has not been studied in patients with moderate to severe renal impairment.

Other approved indications

Systemic-onset juvenile idiopathic arthritis

Tocilizumab received approval by the U.S. Food and Drug Administration for the treatment of systemic-onset JIA. Two phase 2 dose-escalating trials

in 18 white and 11 Japanese children^{24,25} and two phase 3 studies have been conducted. In the first phase 3 study, 56 Japanese children were included in a DBRCT withdrawal design. Of the 43 patients who were included in the double-blind phase, 4 (17%) of 23 patients in the placebo group maintained an ACR core set for a JIA30 response and a CRP concentration of less than 15 mg/L as compared with 16 (80%) of 20 in the tocilizumab group ($P < .0001$). At the end of the open-label extension phase, 47 (98%), 45 (94%), and 43 (90%) achieved an ACR core set for JIA30, JIA50, and JIA70 responses, respectively.²⁶ The largest phase 3 trial involved 112 patients, and at week 12 the primary endpoint (absence of fever and improvement of 30% or greater on at least three of the six variables in the ACR core set for JIA, with no more than one variable worsening by greater than 30%) was met in significantly more patients in the tocilizumab group than in the placebo group (64 of 75 [85%] versus 9 of 37 [24%], $P < .001$).²⁷ At week 52, 80% of the patients who received tocilizumab had at least 70% improvement with no fever, including 59% who had 90% improvement; in addition, 48% of the patients had no joints with active arthritis, and 52% had discontinued oral glucocorticoids. A reduction in joint space narrowing, erosions, epiphyseal irregularity, and subchondral cysts has been observed in other studies.^{28,29}

Castleman disease

Tocilizumab was approved as an orphan drug in Japan for the treatment of Castleman disease and was effective in improving a wide range of disease manifestations, including autoimmune hemolytic anemia, hepatosplenomegaly, pulmonary hypertension, lung lesions, cardiomyopathy, renal manifestations, and IgA nephropathy with cutaneous nodules.^{30,31}

Expanded unapproved indications

Polyarticular juvenile idiopathic arthritis

Tocilizumab was demonstrated to be efficacious in 19 children with polyarticular JIA who failed MTX therapy. At 48 weeks, 100%, 94.1%, 88.2%, and 64.7% achieved 30%, 50%, 70%, and 90% ACR pediatric response rates, respectively. Rheumatoid factor was positive in nine (47%) of the patients. In another report involving 12 children with polyarticular JIA refractory to MTX and other biologics, a good EULAR response was achieved in 9 (75%) of the patients.³²

Adult-onset Still disease

Tocilizumab was reported to be effective for resistant adult-onset Still disease (AOSD) in case reports. The patients included were refractory to corticosteroids, DMARDs, TNFIs, and anakinra. Tocilizumab was effective as monotherapy or when corticosteroids could not be used.³³ It was also successful in managing serious ASOD-related complications such as thrombotic thrombocytopenic purpura, aseptic meningitis, and macrophage activation syndrome.³³⁻³⁵

Systemic lupus erythematosus

The largest study evaluating IL-6 blockade in patients with systemic lupus erythematosus was a phase 1 dose-escalating trial in 16 patients with mild to moderate disease.³⁶ A third of these patients had renal involvement.

Arthritis improved in all the patients, along with a reduction in different serologic markers. Neutropenia occurred in 38% in the 4-mg/kg dose group and in 56% in the 8-mg/kg dose group and resolved after stopping therapy. Infection occurred in 11 patients; none was associated with neutropenia.³⁶

Spondyloarthritis

Several studies reported no benefit with tocilizumab for spondylitis. This has been observed in studies of other IL-6 inhibitors for ankylosing spondylitis. In a case report of two patients with psoriatic arthritis (PsA), tocilizumab failed to improve the skin lesions or arthritis,³⁷ whereas in another patient the psoriatic lesions improved.³⁸

Large-vessel vasculitis (Takayasu and giant cell arteritis)

A number of case reports have shown tocilizumab to be effective in improving ischemic symptoms, normalizing acute-phase reactants, and reducing inflammatory changes in blood vessels when assessed by ultrasound, magnetic resonance angiography, or positron emission tomography. In most of the patients described, the daily steroid requirement was stopped or tapered to a minimal dose. In one case series involving 10 patients (7 with giant cell arteritis, 2 with Takayasu arteritis, and 1 with polymyalgia rheumatica), tocilizumab was shown to be efficacious in all patients up to 6 months.³⁹ The demonstration of persistent large-vessel vasculitis at autopsy in one patient who exhibited a good clinical response implies close monitoring of patients in larger studies of tocilizumab. Disease progression at 1 year was also shown in another report despite clinical and biochemical improvement in a patient with Takayasu arteritis.⁴⁰

Case reports of Cogan syndrome,⁴¹ relapsing polychondritis,⁴² and hepatitis C–negative cryoglobulinemic vasculitis⁴³ state that tocilizumab improves amyloidosis-related symptoms and histologic deposition in the gut, kidney, and heart of patients with RA, JIA, AOSD, and PsA.⁴⁴⁻⁴⁷ Positive observations have also been reported in patients with idiopathic myositis,⁴⁸ Behçet disease,⁴⁹ and TNF receptor–associated periodic syndrome.⁵⁰ Confirmation is needed in all these cases before it is concluded that inhibition of the IL-6 pathway is relevant in these diseases.

EMERGING INTERLEUKIN-6/INTERLEUKIN-6 RECEPTOR INHIBITORS

Several agents are now in development to block the action of IL-6 through either targeting the molecule directly or targeting its surface receptor. Sarilumab is the first fully human IL-6 α monoclonal antibody in development, in contrast to tocilizumab, which is a humanized molecule. Phase 2b and 3 studies are under way to evaluate subcutaneous dosing weekly or twice weekly. Another IL-6 inhibitor, sirukumab, is a human anti-IL-6 monoclonal antibody that is in phase 3 trials to evaluate its efficacy in inadequate responders with RA to both DMARD and TNF; it is administered subcutaneously either twice or four times weekly. Other IL-6 monoclonal antibodies, olkizumab and clazakumab, are in earlier phases of development.

Tumor necrosis factor–blocking therapies

■ PETER C. TAYLOR

- Tumor necrosis factor (TNF) has multiple proinflammatory effects and plays a key role in rheumatoid arthritis.
- Inhibition of TNF with monoclonal antibodies or the TNFR2 soluble receptor leads to a rapid and significant improvement in rheumatoid arthritis activity. Clinical effect is observed within weeks of starting therapy, with ACR20 criteria met in 50% to 70% of patients. Improvement in quality of life, functional status, and structural progression is observed with these therapies.
- Anti-TNF therapy appears more effective in combination with methotrexate than as monotherapy.
- Anti-TNF therapy also significantly benefits those with juvenile arthritis, psoriatic arthritis, psoriasis, and ankylosing spondylitis.
- Serious adverse events are rare but include serious infection, tuberculosis, demyelinating syndromes, increased risk of certain malignancies, and drug-induced lupus.

INTRODUCTION

Biologic agents targeting tumor necrosis factor (TNF) have significantly modified the treatment paradigm for numerous inflammatory disorders and unequivocally validated TNF as a molecular target for therapy. The clinical success and impact of TNF inhibitors (monoclonal antibodies, Fab' antibody fragments or the p75 TNF soluble receptor) have fostered the development of other biologic and small-molecule modulators of proinflammatory cytokines. TNF inhibition is generally well tolerated and capable of ameliorating a variety of inflammatory disorders, although the range of disease phenotypes responding appears to differ with the two biologic approaches to TNF inhibition currently available, so that doses of etanercept effective in rheumatoid and other forms of inflammatory arthritis are not effective in granulomatous diseases such as inflammatory bowel disease, in distinction to the antibodies, which are.

Although TNF plays an important regulatory role in host defense, the amplified and dysregulated production of this cytokine mediates the inflammatory response that characterizes disorders such as rheumatoid arthritis (RA), ankylosing spondylitis (AS), Crohn disease, psoriatic arthritis (PsA), psoriasis, and other inflammatory disorders. Numerous studies have documented the excess production of local and systemic TNF and a reciprocal rise in TNF receptors (TNFRs) in these disorders. Byproducts of TNF-mediated proinflammatory events are also evident. Excessive levels of other proinflammatory cytokines, increased nitric oxide, collagenase, prostaglandins, increased adhesion molecule expression, and evidence of spontaneous erosive synovitis are all found in both human inflammatory diseases and transgenic mice overexpressing TNF.¹ Definitive verification of a primary role for TNF in these disorders came from clinical trials demonstrating the impressive amelioration of disease with TNF blockade.

TNF blockade in RA, PsA, and AS consistently decreases disease activity and improves quality of life, and it lessens radiographic progression of peripheral joint damage. Five biologic agents that inhibit TNF have been approved for use in RA: etanercept, a soluble dimeric TNFR2 immunoglobulin G1 (IgG1)–Fc fusion construct (Enbrel); infliximab, a chimeric anti-TNF- α IgG1 monoclonal antibody (Remicade); adalimumab, a human IgG1 anti-TNF- α monoclonal antibody (Humira); golimumab, a human IgG1 anti-TNF- α monoclonal antibody (Simponi); and certolizumab pegol, a TNF-specific, pegylated Fab' antibody fragment (Cimzia). [Box 63.1](#) lists the

several benefits seen with TNF blockade, including wide approval of these drugs for treatment of many inflammatory disorders, higher remission rates, protection against structural/radiographic deterioration, and possibly a reduced rate of cardiovascular events in RA patients.

MECHANISM OF ACTION

TNF and TNFRs are members of a family of molecules (including Fas ligand/Fas, CD40 ligand/CD40) possessing crucial regulatory functions that include cellular activation and apoptosis. TNF is an attractive therapeutic target owing to its abundant expression in the RA joint and plethora of proinflammatory effects that include regulation of other proinflammatory mediators.

TNF- α is made intracellularly, and the 26-kDa precursor transmembrane form is cleaved off by a specific metalloproteinase, TNF- α -converting enzyme, to produce soluble biologically active TNF. This molecule aggregates as a homotrimer in its active form. TNF- α and the closely related TNF- β (also known as *lymphotoxin- α*) equally bind the TNFR1 (p55, CD120a) and TNFR2 (p75, CD120b) receptors present on many cell types. The TNFR has an extracellular domain that can also be cleaved and released as a soluble TNFR and functions as a naturally occurring inhibitor.

The TNFRs differ in their binding abilities and signaling properties; these differences also reflect the differences in their primary functions. The presence of both receptors on nearly all cell types (except erythrocytes) underscores the wide-ranging biologic effects of TNF. Whereas TNFR1 is constitutively expressed on all cell types, TNFR2 is induced and expressed in larger amounts on hematopoietic and endothelial cells. Although binding of TNF to its receptor initiates a cascade of biologically profound events, both cell-bound and circulating TNF- α may also be bound to soluble TNFRs serving as natural, counterregulatory TNF antagonists. The extracellular domain of cell-bound TNFRs may be cleaved off (especially in an inflammatory milieu) to circulate in soluble form, where it binds TNF and ultimately is excreted by the kidney. The binding of TNFR1 and TNFR2 to TNF- α appears to be similar, with the main difference lying in the dissociation kinetics. Thus, although the binding of TNFR1 is static and almost irreversible (due to slow off-rate), the binding of TNFR2 is more dynamic owing to a more rapid off-rate. It appears that the physiologic activities of soluble TNF are largely mediated through the TNFR1 receptor, whereas TNFR2 is involved in ligand passing. The binding of TNF- α to its receptor can initiate several signaling pathways, including the activation of transcription factors (e.g., nuclear factor κ B), protein kinases (e.g., c-Jun N-terminal kinase [JNK], p38 MAP kinase), and proteases (e.g., caspases) that markedly impact immune and inflammatory responses.

TNF- α primarily mediates inflammation by promoting cellular activation and trafficking of leukocytes to inflammatory sites. The biologic properties affected by TNF are listed in [Box 63.2](#). TNF- α is produced primarily by monocytes and macrophages but may also be produced by other cell types (e.g., B cells, T cells, mast cells, fibroblasts). TNF- α may further contribute to the pathogenesis of RA by induction of proinflammatory cytokines such as interleukin-1 (IL-1) and IL-6, enhancement of leukocyte migration by increasing endothelial layer permeability and expression of adhesion molecules by endothelial cells and leukocytes, activation of neutrophils and eosinophils, induction of the synthesis of acute-phase reactants, and induction of tissue-degrading enzymes (matrix metalloproteinase enzymes) produced by synoviocytes and/or chondrocytes.

Although all biologic TNF inhibitors share many biologic, clinical, and adverse effects, there are differences among them beyond their pharmacokinetics. The monoclonal antibodies infliximab, adalimumab, golimumab, and certolizumab are specific for TNF- α ; etanercept binds both TNF- α and

lymphotoxin- α . Infliximab, adalimumab, and golimumab are IgG1 antibodies, and etanercept contains an IgG1 portion; certolizumab is a pegylated Fab' fragment lacking an Fc portion. In addition to sharing the ability to inhibit TNF, all five agents bind to TNF with high affinity, and all three monoclonal antibodies are virtually the same in their ability to neutralize soluble and transmembrane TNF. The induction of cell lysis in a cell line overexpressing TNF- α has been demonstrated in *in-vitro* studies of infliximab and adalimumab (Fig. 63.1).

The first formal proof that TNF- α regulates other proinflammatory cytokines *in vivo* was the observation that there is a rapid reduction in serum IL-6 concentrations, closely followed by falling serum C-reactive protein (CRP) levels, following administration of infliximab.^{2,3} Although IL-1 concentrations are often below the limit of detection in the peripheral blood of RA patients, when it is detectable, downregulation has been reported in a proportion of patients.⁴ In a small study in which repeat synovial biopsy specimens were obtained before and 2 weeks after a single infusion of 10 mg/kg of infliximab, computerized image analysis of sections stained for cytokine-producing cells demonstrated a reduction in synovial IL-1 α and IL-1 α in a subgroup.⁵ The benefits of anti-TNF therapy are not mediated by upregulation of endogenous proinflammatory cytokine inhibitors, because

circulating IL-1 receptor antagonist (IL-1ra) and soluble TNFR levels fall after infliximab infusion.³

A major mechanism of action of TNF inhibitors is likely to be modulation of inflammatory cell traffic. A dose-dependent rise in peripheral blood lymphocyte counts is observed following infliximab infusion, with a maximum rise within 24 hours of treatment.⁶ This is mediated by modulation of both arms of the inflammatory cell recruitment cascade. There is reduced histologic expression of synovial cytokine-induced vascular adhesion molecules, such as E-selectin and VCAM-1, following anti-TNF treatment,⁷ a significant dose-dependent reduction in soluble serum E-selectin and intercellular adhesion molecule 1 concentrations,⁶ and a significantly diminished immunohistologic expression of the chemokines IL-8 and MCP-1, with a trend toward reduction in a number of other chemokines.⁸

Infliximab therapy is also associated with a reduction in numbers of synovial tissue macrophages and lymphocytes.^{7,8} However, the definitive confirmation that TNF blockade reduces leukocyte traffic to inflamed joints was obtained in an open-label clinical trial demonstrating a 40% to 50% decrease in retention of autologous indium-111-labeled granulocytes in the hands, wrists, and knees 2 weeks after infliximab treatment.⁸ There is a reduction in the marginating granulocyte pool after infliximab treatment, an observation that would normally be associated with a rise in peripheral blood granulocyte counts.⁹ However, in contrast to peripheral blood lymphocyte counts, the numbers of peripheral blood granulocytes decrease after infliximab dosing with maximal changes within 24 hours. The reason for this is that myeloid cell production is reduced secondary to downregulation of granulocyte-macrophage colony-stimulating factor as a consequence of TNF blockade. Because of the short circulating half-life of the granulocyte of approximately 8 hours, a diminished rate of cell production dominates the peripheral blood picture.

One factor contributing to the rapid reduction in joint swelling after anti-TNF therapy is likely to be a reduction in tissue edema and capillary leak, mediated by vascular endothelial growth factor (VEGF), a cytokine implicated in new blood vessel formation and found to be elevated in the serum of RA patients.¹⁰ Serum concentrations of VEGF show a dose-dependent reduction following infliximab infusions, but without normalization. There is also reduction in synovial vascular density and in particular a reduction in angiogenesis, as assessed by diminished number of vessels expressing the $\alpha_v\beta_3$ integrin.¹¹ The vascular signal on quantitative power Doppler imaging is also significantly reduced following infliximab therapy.^{12,13}

A marked reduction in circulating concentrations of the precursors of the matrix metalloproteinase enzymes MMP-1 and MMP-3¹⁴ and a significant reduction in synovial tissue expression of matrix metalloproteinases was noted.¹⁵ Serum levels of osteoprotegerin (OPG) and soluble receptor activator of nuclear factor κ B ligands (sRANKL), both of which are elevated in RA sera compared with normal sera, are normalized following infliximab therapy without influencing the OPG-sRANKL ratio.¹⁶ These observations predicted the beneficial effects on radiographic erosions with anti-TNF inhibitors.

One hypothesis for the failure of etanercept to work in Crohn disease, in contrast to the marked benefits demonstrated with monoclonal antibodies to TNF- α , is that the antibodies may cause an increase in apoptosis of lamina propria and peripheral T cells through caspase-dependent mechanisms. This topic remains controversial, and the relevance of modulation of apoptosis

BOX 63.1 BENEFITS OF TUMOR NECROSIS FACTOR BLOCKADE

- Efficacy, safety, and approval for use in numerous inflammatory states: rheumatoid arthritis (RA), juvenile arthritis, psoriasis, psoriatic arthritis, ankylosing spondylitis, Crohn disease, and ulcerative colitis
- Increased odds of remission in both randomized controlled trials and clinical practice (in both early and established RA)
- Significant disease modification as assessed by radiographic studies
- Dramatic normalization of acute-phase reactants
- Reduced levels of serum rheumatoid factor and cyclic citrullinated peptide antibodies
- Decreased frequency of cardiovascular events in RA patients

BOX 63.2 BIOLOGIC EFFECTS OF TUMOR NECROSIS FACTOR- α

- Adhesion molecule expression (E-selectin, ICAM-1)
- Synthesis of other proinflammatory cytokines (IL-1, IL-6, GM-CSF)
- Synthesis of chemokines (e.g., RANTES, IL-8, MIP-1)
- Activation of numerous cell types (T cells, B cells, macrophages)
- Inhibition of regulatory T cells
- Matrix metalloproteinase induction
- Upregulation of RANK ligand expression
- Induction of apoptosis
- Antiviral and antitumor effects of tumor necrosis factor

GM-CSF, granulocyte-macrophage colony-stimulating factor; ICAM-1, intercellular adhesion molecule 1; IL, interleukin; MIP-1, macrophage inhibitory protein 1.

Fig. 63.1 Infliximab is a mouse/human chimeric monoclonal anti-tumor necrosis factor (TNF) antibody of immunoglobulin G1 (IgG1) isotype. Adalimumab and golimumab are fully human IgG1 monoclonal anti-TNF antibodies. Etanercept is a fusion protein of the p75 (TNF receptor 2) and the Fc portions of IgG1. Certolizumab pegol is a pegylated Fab' fragment of a humanized IgG1 monoclonal anti-TNF antibody.

as the mechanism of action of TNF inhibitors in RA is unclear. In one study, decreased synovial cellularity was reported as early as 48 hours after infliximab administration, but with no corresponding evidence of apoptosis.¹⁷ In another study, however, apoptosis in synovial macrophages was reported to be induced by both etanercept and infliximab, with a corresponding increase in active caspase-3 expression. No increase in lymphocyte apoptosis was observed, however.¹⁸

Approved indications and practical use

Table 63.1 details U.S. Food and Drug Administration (FDA)–approved indications for the use of anti-TNF therapy. TNF blockers were initially approved in RA, juvenile arthritis, and PsA for patients with moderately to severely active disease in whom an adequate trial of methotrexate (MTX) or other disease-modifying antirheumatic drugs (DMARDs) had failed. TNF blockers were also indicated for the control of signs and symptoms and the prevention of functional or radiographic deterioration in RA and PsA. Following the findings of large controlled trials in early RA patients, the FDA recommendations for infliximab, adalimumab, and etanercept were modified to allow their use as the initial DMARD in RA, and thus the requirement of failure of MTX (or other DMARD) was removed (see Table 63.1). Therefore, although MTX and TNF inhibitors appear to be equally effective in clinical trials, TNF inhibitor therapy has been established as yielding better radiographic outcomes (alone or in combination with MTX). Despite the clinical and radiographic potency of TNF blockade, particularly with concomitant MTX therapy, the circumstances in which this combination should be initiated as a first-line therapy have not been firmly established; a major consideration is the cost effectiveness of biologic therapies within the context of particular health care economies.

The optimal candidate for TNF inhibition has not been defined. The top indications for TNF inhibitor use in RA include (1) failure of MTX, (2) failure of multiple DMARDs, (3) physician assessment of active disease, (4) radiographic erosions, and (5) functional disability. The 2010 EULAR guidelines¹⁹ for management of RA recommend that, in patients showing insufficient response to MTX and/or other synthetic DMARDs with or without glucocorticoids, a TNF inhibitor be initiated and, unless contraindicated, be administered in combination with MTX.

Relative contraindications to TNF inhibitor use include overlap syndromes, a history of demyelinating disorder (multiple sclerosis, optic neuritis), congestive heart failure, and pregnancy. Absolute contraindications include untreated active or latent tuberculosis (Box 63.3). The clinician should always carefully consider the anticipated hazards versus potential benefits before proceeding with TNF inhibition.

Unless there is a contraindication to its use, MTX should be considered the front-line DMARD of choice in RA. Although other oral DMARD compounds may subsequently be considered as a monotherapy replacement,

TNF inhibitors are among the most effective second-line therapies available, especially in patients with active RA not controlled by MTX therapy at an adequate duration and dose.

In cases in which MTX therapy has been initiated and administered at appropriate dosages for no longer than 3 to 6 months but low disease activity has not been reached, it remains unclear whether a switch to combination DMARDs is as effective as addition of a biologic anti-TNF agent. Data from the BeST trial suggests that MTX plus TNF inhibitor is superior to add-on or sequential combination DMARD regimens.²⁰ In the SWEFOT trial, patients with early RA had initial MTX treatment, and only after this agent failed were they randomly assigned to two therapeutic strategies: the addition of sulfasalazine plus hydroxychloroquine, or the addition of infliximab.²¹ After 1 year, 25% of patients receiving the former combination and 39% of patients receiving the latter had achieved a EULAR good response, and the difference was statistically significant. Data from the Randomized Comparative Effectiveness Study of Oral Triple Therapy versus Etanercept plus MTX in Early, Aggressive Rheumatoid Arthritis (TEAR) suggested that treatment with the combination of MTX plus etanercept provided better radiographic benefit but similar clinical response compared with oral triple therapy.²²

DMARD-naïve patients with poor prognostic markers might be considered for combination therapy with MTX plus a biologic agent in very exceptional situations. However, the EULAR recommendations for treatment of RA consider that, in general, this approach is not cost effective.¹⁹ Such patients must manifest a weighty combination of risk factors that portends a severe outcome, including active polysynovitis, radiographic erosions, seropositivity for rheumatoid factor and/or anti-cyclic citrullinated peptide antibodies, functional impairment, and sustained elevations of acute-phase markers. The identification of such high-risk patients mandates the combined use of MTX and TNF inhibition because studies have consistently

BOX 63.3 RELATIVE CONTRAINDICATIONS TO THE USE OF TUMOR NECROSIS FACTOR INHIBITORS

- Systemic lupus erythematosus, lupus overlap syndrome
- Multiple sclerosis, optic neuritis, demyelinating disorders
- Current, active, serious infection
- Recurrent or chronic infection
- Untreated latent or active mycobacterial infection
- Hepatitis B infection
- Congestive heart failure
- Pregnancy

TABLE 63.1

U.S. Food and Drug Administration–approved indications for tumor necrosis factor- α inhibitors

Indication	Etanercept	Infliximab	Adalimumab	Golimumab	Certolizumab
Rheumatoid arthritis	Yes ^a	Yes ^b	Yes ^a	Yes ^b	Yes
Early rheumatoid arthritis	Yes	Yes	Yes	—	—
Polyarticular juvenile arthritis	Yes ^c	—	—	—	—
Psoriatic arthritis	Yes ^d	Yes ^e	Yes ^e	Yes	Yes
Ankylosing spondylitis	Yes ^f	Yes ^f	Yes ^f	Yes	Yes
Psoriasis	Yes ^g	Yes	—	—	—
Crohn disease	—	Yes ^h	Yes ^h	—	Yes
Ulcerative colitis	—	Yes ⁱ	Yes	—	—

^aIndicated for reducing signs and symptoms, inhibiting the progression of structural damage, and improving physical function in patients with moderately to severely active rheumatoid arthritis. It can be initiated alone or in combination with methotrexate (MTX).

^bInfliximab and golimumab are approved for use in combination with MTX only.

^cIndicated for reducing signs and symptoms of moderately to severely active polyarticular juvenile rheumatoid arthritis in patients who have had an inadequate response to one or more disease-modifying antirheumatic drugs.

^dOnly etanercept is indicated to inhibit the progression of structural damage and improve physical function in patients with moderately to severely active psoriatic arthritis. It can be used in combination with MTX in patients who do not show adequate response to MTX alone.

^eIndicated for reducing signs and symptoms of active arthritis in patients with psoriatic arthritis.

^fIndicated for reducing signs and symptoms in patients with active ankylosing spondylitis.

^gIndicated for the treatment of adult patients (>18 yr) with chronic moderate to severe plaque psoriasis who are candidates for systemic therapy or phototherapy.

^hIndicated for reducing signs and symptoms and inducing or maintaining clinical remission in patients with moderately to severely active Crohn disease who have had an inadequate response to conventional therapy. Also indicated for reducing the number of enterocutaneous and rectovaginal fistulas and maintaining fistula closure in fistulizing Crohn disease.

ⁱOnly infliximab is indicated for reducing signs and symptoms, achieving clinical remission and mucosal healing, and eliminating corticosteroid use in patients with moderately to severely active ulcerative colitis who have had an inadequate response to conventional therapy.

shown that clinical and radiographic outcomes are best when this combination is used instead of TNF inhibitor or MTX alone.

In addition to the rapid onset of effect is the enhanced well-being and improvement in fatigue reported by patients receiving TNF blockade. The mechanism for this effect is unknown. The popularity of these agents is evident from the growth in their use worldwide. Nonetheless, several factors have limited their more widespread use, including patient or physician reluctance, limited or variable coverage by third-party insurance carriers, toxicity concerns, and in particular, high costs.

ADALIMUMAB (HUMIRA)

Adalimumab was approved in December 2002 after an extensive development program.

Pharmacology

Adalimumab is a fully human IgG1 anti-TNF- α monoclonal antibody produced by phage display with a terminal half-life of 10 to 20 days (mean, 14 days), which permits every-other-week dosing. After a single 40-mg subcutaneous dose, the maximum serum concentration is achieved within 131 ($\pm$ 56) hours. The antibody binds circulating and cell-bound TNF- α and blocks its interaction with p55 and p75 receptors but does not interact with lymphotoxin (TNF- β). The drug induces cell lysis of TNF-expressing cells (in the presence of complement). Concomitant MTX therapy reduces the clearance of adalimumab by 29% to 44%. It is unknown if adalimumab pharmacokinetics is altered in the setting of renal or hepatic impairment.

Indications and use

Adalimumab is indicated to reduce signs and symptoms, inhibit radiographic damage or progression, and improve physical function in moderate to severe RA that is unresponsive to an adequate trial of one or more DMARDs. It is also approved for treatment of PsA, AS, psoriasis, Crohn disease, and ulcerative colitis. Adalimumab may be used as monotherapy or in combination with MTX; the recommended dosage is 40 mg administered subcutaneously every other week. Higher dosages (e.g., 80 mg every other week) were used during drug development but were not shown to be more effective in short-term trials. A minority of patients may require dose escalation (e.g., 40 mg weekly), in particular those receiving adalimumab monotherapy. In the PREMIER early RA trial, dose escalation was permitted for

those not meeting American College of Rheumatology 20% improvement criteria (ACR20). Patients receiving adalimumab monotherapy were more likely to need escalation to weekly dosing than those receiving combined adalimumab and MTX (25% vs. 11%, respectively).²³ Whether dose escalation to weekly adalimumab in patients taking MTX will lead to a better clinical response is less certain.

Adalimumab in rheumatoid arthritis pivotal trials

A single dose of adalimumab^{23a} produced significant and rapid clinical improvement, reduced acute-phase reactants, increased circulating lymphocyte counts, and significantly reduced systemic IL-6 and IL-1ra levels for at least 2 weeks. In controlled dose-ranging monotherapy studies, ACR20 response rates ranged from 46% to 73% (Table 63.2). In a placebo-controlled monotherapy trial involving 544 RA patients, a dose-dependent rise in ACR response rates was seen, with 46% of those receiving 40 mg every other week achieving an ACR20 response.²⁴

The ARMADA trial studied adalimumab in 271 RA patients with chronic disease and an inadequate response to MTX.²⁵ In this 6-month multicenter trial, patients continued to receive stable doses of MTX (mean, 16 to 17 mg/wk) and received placebo or 20 mg, 40 mg, or 80 mg of adalimumab every 2 weeks. ACR20 response rates were 14%, 48%, 66%, and 66% for those taking placebo, 20 mg adalimumab, 40 mg adalimumab, and 80 mg adalimumab, respectively. Another pivotal trial (DE019) examined efficacy and radiographic outcomes in a 52-week trial in 619 patients in which adalimumab 20 mg or 40 mg every other week or placebo was given to MTX partial responders.²⁶ ACR20 response rates after 52 weeks were 24%, 55%, and 59% in the placebo, 20 mg adalimumab, and 40 mg adalimumab groups, respectively. Responses were sustained in the 457 patients who went on to receive long-term open-label adalimumab. Radiographic progression, as measured by modified Sharp scores, was significantly worse in the placebo group (+2.7 Sharp units) compared with the groups receiving adalimumab 20 mg/wk (+0.7 Sharp units) and 40 mg every other week (+0.1 Sharp units).

The PREMIER trial established the efficacy of adalimumab in early RA (see Table 63.2). In this 2-year trial in patients with early RA (less than 3 years' duration), 799 DMARD-naïve patients received either adalimumab, MTX, or the combination of MTX and adalimumab.²³ Adalimumab and MTX were equipotent with regard to clinical outcomes (ACR20/50/70 responses, Disease Activity Score [DAS] remission), whereas the combined use of MTX and adalimumab was significantly better. ACR70 response rates and 6-month sustained, major clinical response rates were twofold higher with MTX plus adalimumab than with adalimumab alone (47% vs. 27% and

Fig. 63.2 * = $P < 0.001$ versus adalimumab alone and versus MTX alone. (From Breedveld FC, Weisman MH, Kavanaugh AF, et al. The PREMIER study: a multicenter, randomized, double-blind clinical trial of combination therapy with adalimumab plus MTX versus MTX alone or adalimumab alone in patients with early, aggressive rheumatoid arthritis who had not had previous MTX treatment. *Arthritis Rheum* 2006;54:26-37.)

49% vs. 25%, respectively). Outcomes on primary measures included a 62% ACR50 response rate and a minimal change (+1.3 Sharp unit) in total Sharp score for those receiving MTX plus adalimumab for 12 months (Fig. 63.2).

ETANERCEPT (ENBREL)

In 1999 etanercept became the first anti-TNF therapy approved for RA by the FDA.

Pharmacology

Etanercept is a dimeric fusion construct that links two TNFR2 receptors to the Fc portion of IgG, containing domains CH2 and CH3 and the hinge region. Etanercept is produced in Chinese hamster ovary cells and has a

molecular weight of 150 kDa. It is capable of binding two circulating or cell-bound TNF- α molecules and inhibits the binding of TNF- α and TNF- β (lymphotoxin) to TNFRs. In contrast to the monoclonal antibodies, etanercept does not induce cell lysis or apoptosis of TNF-expressing cells. The half-life of etanercept in adult RA patients is 102 hours (± 30 hours) with a range of 4.1 to 12.5 days. Pharmacokinetics in children (older than age 4) is assumed to be similar to that in adults, although drug clearance may be reduced in children between the ages of 4 and 8 years. Steady-state serum concentrations were comparable in patients with RA treated with 50 mg once weekly and with 25 mg twice weekly. The route of clearance from the circulation is unclear, although it is thought to be mediated through Fc binding by the reticuloendothelial system. MTX has no effect on the pharmacokinetics of etanercept.

Indications and use

Etanercept is indicated in patients with established or early RA to reduce signs and symptoms, inhibit structural damage, and improve physical function in those with moderate to severe disease. Etanercept may be used alone or in conjunction with MTX. In adult RA patients, etanercept is given by self-administered subcutaneous injection at 50 mg once a week (or 25 mg twice weekly). In a controlled clinical trial, dose escalation to 100 mg weekly was not associated with increased efficacy in patients with active disease despite receiving long-term etanercept 50 mg/wk plus MTX.²⁷

Etanercept is also approved for use in patients with active, moderate to severe polyarticular juvenile arthritis, PsA, and AS (see Table 63.1). It is approved for moderate to severe plaque psoriasis at a higher dosage of 50 mg twice weekly for 3 months followed by a maintenance dose of 50 mg once weekly.

Etanercept in rheumatoid arthritis pivotal trials

The efficacy of etanercept was established in four pivotal clinical trials encompassing 1637 RA patients (Table 63.3). These trials consistently demonstrate impressive clinical outcomes, with ACR20 response rates ranging from 59% to 75% and ACR70 response rates of 15% to 40% after 6 to 12 months of therapy.

A 6-month randomized, controlled study compared placebo and etanercept (10 mg or 25 mg) subcutaneously twice weekly²⁸; 59% ACR20 and 15% ACR70 response rates were seen in patients taking etanercept 25 mg twice weekly, with lower responses seen with the 10-mg dose. When etanercept was added to long-term MTX, patients receiving etanercept and MTX showed a 71% ACR20 response rate compared with a 27% rate in the placebo plus MTX group.²⁹ Many of these patients were enrolled in a long-term open-label observational study and exhibited static ACR20, ACR50, and ACR70 response rates over 3 years. Importantly, sustained efficacy allowed for a 68% to 85% decrease in MTX or prednisone, and 39% to 59% of patients were able to discontinue MTX and prednisone use after 3 years.³⁰

Etanercept was the first biologic therapy tested head to head against MTX in an early RA (ERA) trial. This 12-month trial enrolled 632 patients with early RA (mean disease duration, 11 months), who received etanercept (10 or 25 mg twice weekly) or MTX 20 mg/wk.³¹ After 12 months, the MTX-treated and 25-mg etanercept-treated groups fared equally well, with ACR20 response rates of 65% and 72%, respectively. The only significant group difference in clinical effects was the more rapid onset of effect in those treated with etanercept in the first 4 months. Serious infectious events were infrequent in both groups (less than 3%). In the second year, a trend toward higher ACR20 response rates was seen in the etanercept group compared with the MTX group (72% vs. 59%).³²

The ERA trial showed that radiographic progression was diminished by both agents when assessed after 6, 12, and 24 months of therapy (Fig. 63.3). In the first year, modified Sharp scores showed little change in either the MTX group (1.3 units) or etanercept group (0.8 units), yet results for both were significantly better than their projected rates of radiographic deterioration (estimated to be approximately 9 Sharp units/yr). In the second year of the trial, significant differences were seen, with etanercept patients showing an increase of only 1.3 Sharp units (no progression in 63%) and MTX patients showing an increase of 3.2 Sharp units (no progression in 51%). The ERA trial was pivotal in demonstrating the potency of both MTX and etanercept in patients with early, aggressive RA. The additional radiographic advantage of TNF inhibition over MTX in early disease was seen largely in those with erosions at entry into the study.

The TEMPO trial reported the comparative efficacy of MTX, etanercept, and the combination of etanercept plus MTX in 682 patients with active RA with a mean disease duration of 7 years.³³ At both 12 and 24 months the combination of etanercept and MTX was significantly more effective than

Fig. 63.3 ERA trial: etanercept in early rheumatoid arthritis. (From Genovese MC, Bathon JM, Martin RW, et al. Etanercept versus MTX in patients with early rheumatoid arthritis: two year radiographic and clinical outcomes. *Arthritis Rheum* 2002;46:1443–50.)

monotherapy with either MTX or etanercept alone (see Table 63.3). At 24 months the combination group demonstrated impressive ACR20 (86%) and ACR70 (49%) response rates and DAS remissions (38%). Comparison of MTX-naïve and previously treated MTX patients failed to show significant differences in outcomes. The mean total Sharp score was decreased by 0.56 units in patients receiving combination etanercept plus MTX and 78% had no radiographic worsening. By comparison, total Sharp scores were increased in those taking etanercept alone (+0.5 units) or MTX alone (+2.8 units), and 60% to 68% showed no radiographic progression while taking MTX or etanercept, respectively. This study underscores the potential additive

clinical and radiographic protection afforded by the combination of MTX and TNF therapy, especially in patients with aggressive disease.

The COMET trial³⁴ compared the effects of a combination of etanercept and MTX with MTX alone in 542 MTX-naïve patients with early RA (duration of 3 months to 2 years). Half of the patients receiving combined treatment achieved DAS28 remission (less than 2.6) and 80% achieved radiographic nonprogression compared with 28% and 59%, respectively, of those taking MTX alone. For a majority of patients with early severe RA, clinical remission and radiographic nonprogression are achievable goals within 1 year of combined treatment with etanercept plus MTX.³⁴

INFLIXIMAB (REMICADE)

Infliximab was first approved for use in moderate to severe Crohn disease in 1998 and was approved in 1999 for use in RA.

Pharmacology

Infliximab is a chimeric anti-TNF monoclonal antibody that combines human IgG1K (constant region) with a murine Fv (variable) region and is produced in a murine myeloma cell line transfected with cloned DNA coding for cA2. Infliximab binds with high affinity to both soluble and membrane-bound TNF and is capable of neutralizing TNF *in vitro* and *in vivo*. This antibody can mediate cytotoxicity of TNF-expressing cells *in vitro* and is capable of inducing cell lysis of TNF-expressing cells via antibody-dependent cellular cytotoxicity *in vitro*. Infliximab binds TNF- α but not lymphotoxin (TNF- β). The median terminal half-life in patients with RA and Crohn disease is 8 to 9.5 days (mean, 210 hours) at doses of 3 to 10 mg/kg. Infliximab exhibits a linear dose-related pharmacokinetic profile at doses ranging from 3 to 20 mg/kg. Pharmacokinetic studies in the elderly and in patients with renal or hepatic dysfunction have not been done. Infliximab serum concentrations tended to be slightly higher when the drug is used along with MTX (7.5 mg once a week). The development of human antichimeric antibodies (HACA) has been shown to increase clearance and reduce serum levels of infliximab.

Indications and dosing

In established and early RA, infliximab (with MTX) is indicated to reduce signs and symptoms, inhibit radiographic progression, and improve physical

function in patients with moderately to severely active RA. Concurrent use of MTX (7.5 mg/wk) with infliximab has been shown to limit the immunogenic response to the construct (e.g., HACA formation). This is particularly relevant at lower doses (e.g., infliximab 3 mg/kg), at which immunogenicity is more likely than at higher doses (e.g., 10 mg/kg). Infliximab monotherapy (without MTX) is customary in Crohn disease, AS, ulcerative colitis and psoriasis, in which higher doses are usually employed.

In RA, the recommended dosage is 3 mg/kg given initially at weeks 0, 2, and 6 and thereafter every 8 weeks in combination with MTX. Infliximab is given as an intravenous infusion over 2 hours. Escalation of dose (up to 10 mg/kg) or frequency (every 4 to 6 weeks) may be necessary in some, but higher dosages may be associated with a higher frequency of serious infections (see later). Changes in dosing or dose intervals to maintain clinical efficacy may be needed. The loss of efficacy and the “dose creep” phenomenon are most common after the first year of therapy and may be due to physician-patient efforts to reduce the use of other adjunctive therapies (e.g., MTX, nonsteroidal antiinflammatory drugs, prednisone). Although 26% of patients receiving 3 mg/kg have undetectable infliximab levels at 8 weeks, shorter intervals (e.g., 4 weeks) and higher doses (e.g., 10 mg/kg) were less likely to result in undetectable levels.^{35,36} It was suggested that shorter dosing intervals would yield higher trough levels than would higher doses at the same intervals. For patients demonstrating a loss of efficacy, the clinician should first optimize the dose of MTX and then, if necessary, decrease dosing intervals (e.g., every 4 to 6 weeks) and then employ higher doses (up to 10 mg/kg).

Infliximab is also indicated for active adult and pediatric Crohn disease (including fistulizing disease), ulcerative colitis, AS, PsA, and psoriasis at a starting dose of 5 mg/kg. The initial dosing regimen is similar to that for RA (see earlier), and infliximab can be given every 8 weeks (or every 6 weeks in AS) thereafter.

Clinical efficacy of infliximab in rheumatoid arthritis

The efficacy and safety of infliximab in RA were initially established in monotherapy trials in which infliximab was administered after a DMARD washout. An 8-week open-label trial³⁷ demonstrated equivalent efficacy for two different regimens of infliximab: (1) two infusions of 10 mg/kg 2 weeks apart and (2) four monthly infusions of 5 mg/kg. Clinical benefits were noted after week 3 and were maximal by week 6 with normalization of CRP levels in nearly 90% of patients. Following the last infusion, clinical responses lasted a median of 14 weeks (range, 8 to 25 weeks). Another placebo-controlled monotherapy trial administering a single infusion of 1 mg/kg or 10 mg/kg demonstrated significant improvement by week 4, with Paulus 20% responses achieved in 44% and 79% of the low-dose and high-dose groups, respectively.³⁸ Eight responding patients went on to receive repeated infusions when clinical relapse became evident. In this group treated with infliximab alone, a trend toward shorter response intervals showed some correlation with the presence of HACA.

In another study the safety and immunogenicity of infliximab (1, 3, or 10 mg/kg) when given with or without MTX for 26 weeks was reported.³⁹ A Paulus 20% response was seen in 60% of patients receiving 3 or 10 mg/kg. Additive responses were seen with MTX (7.5 to 15 mg/wk) plus infliximab. After 26 weeks, HACA responses were seen in 53%, 21%, and 7% of those receiving 1 mg/kg, 3 mg/kg, and 10 mg/kg, respectively. The concurrent use of low-dose MTX further decreased HACA responses to 15%, 7%, and 0%, respectively. Larger multicenter trials further established the efficacy and safety of long-term infliximab administration on background MTX therapy in RA (Table 63.4). The ATTRACT trial was a 428-patient placebo-controlled trial of infliximab (3 mg/kg or 10 mg/kg) given every 4 or 8 weeks in patients with active RA receiving MTX weekly.⁴⁰ Patients who received infliximab (3 or 10 mg/kg) in addition to background MTX therapy showed significantly higher ACR20 responses (50% to 58%) than those taking MTX alone (20%) at 30 weeks. After 54 weeks ACR20 response rates were 42% to 59% in the 3-mg and 10-mg/kg groups.⁴⁰ Radiographic damage was progressive in the group receiving MTX plus placebo, increasing by a mean of 7 Sharp units at 1 year. By contrast, both the infliximab-treated groups (3 or 10 mg/kg) showed little change (1.3 and 0.2 units, respectively) after 12 months. At 2 years, 22% of placebo-treated patients showed no evidence of radiographic progression, whereas 43% to 47% of the 3-mg/kg group and 64% of the 10-mg/kg group showed no evidence of radiographic change. In patients without erosions at entry, infliximab plus MTX was revealed to be superior to MTX alone in halting further radiographic progression.⁴¹

The 12-month ASPIRE trial examined the effects of MTX and infliximab in 1049 patients with early RA with a mean disease duration of 7 months.⁴² All patients received MTX weekly (20 mg/wk) and either placebo or

infliximab (3 mg/kg or 6 mg/kg). MTX/placebo-treated patients exhibited good ACR20 (54%) and ACR70 (21%) response rates and DAS remissions (15%); patients treated with MTX/infliximab showed significantly higher ACR20 (62% to 66%) and ACR70 (33% to 37%) response rates and DAS remissions (21% to 33%) at 54 weeks (Fig. 63.4). Radiographic progression was observed primarily in those patients treated only with MTX (see Fig. 63.4). Although 45% of the MTX/placebo-treated patients showed no progression, those receiving infliximab plus MTX demonstrated greater protection from progression in radiographic scores (no progression in 58% to 59%).

Two trials have suggested that the early use of infliximab in patients with new-onset RA may allow for its subsequent discontinuation with maintenance of efficacy using MTX therapy alone.^{20,43} A pilot study of 12 months of MTX and infliximab therapy in 20 high-risk patients with early RA resulted in clinical and magnetic resonance imaging (MRI) benefits that were sustained for a year after infliximab was withdrawn.⁴³ The BeST trial compared four treatment strategies for DMARD and biologic use in patients with early RA.²⁰ DMARD switch or add-on monotherapy was compared with a COBRA-like combination DMARD regimen and combined MTX and infliximab. The protocol called for the cessation of infliximab if remission was achieved after 9 months of therapy. After 4 years, more than half of infliximab/MTX-treated patients discontinued infliximab while maintaining a DAS of less than 2.4, and 18% of patients stopped both MTX and infliximab (drug-free remission) without recurrence or radiographic progression.⁴⁴ A *post-hoc* analysis of patient data for the four strategy limbs suggested that using MTX plus infliximab as initial treatment in patients with recent-onset RA is more effective than reserving MTX plus infliximab for patients in whom traditional DMARD therapy fails, with more improvement in HAQ scores over time, more infliximab discontinuation, and less progression of joint damage.⁴⁵ Initial combination therapy led to significantly faster improvement in all patient-reported measures.⁴⁶ The observation that drug-free or MTX-maintained remission may be maintained without ongoing TNF inhibition is an exciting development that requires further confirmation.

(From St. Clair EW, Van Der Heijde DM, Smolen JS, et al; Active-Controlled Study of Patients Receiving Infliximab for the Treatment of Rheumatoid Arthritis of Early Onset Study Group. Combination of infliximab and MTX therapy for early rheumatoid arthritis: a randomized, controlled trial. *Arthritis Rheum* 2004;50:34320-43.)

CERTOLIZUMAB PEGOL (CIMZIA)

Certolizumab was first approved for use in moderate to severe Crohn disease in 2008 and was subsequently approved for treatment of RA in 2009.

Pharmacology

Certolizumab pegol is a TNF-specific, pegylated Fab' antibody fragment (see Fig. 63.1). The Fab' fragment was engineered with a single hinge-region free-cysteine residue, which enables site-specific attachment of polyethylene glycol (PEG) without affecting the ability of the Fab' fragment to bind and neutralize TNF. The attachment of a 40-kDa PEG moiety to the Fab' fragment markedly increases the half-life of certolizumab to one comparable with that of a whole antibody product. Because of the absence of an Fc region, certolizumab pegol does not mediate cell killing either directly through fixation of complement or via recruitment of effector cells.⁴⁷ Unlike the monoclonal antibodies adalimumab, infliximab, and golimumab, which are all bivalent with specificity for the monomeric subunit of homotrimeric TNF- α , certolizumab is univalent for the same ligand and therefore cannot cross-link membrane-bound TNF- α or soluble homotrimers, the consequence of the latter being that there is no formation of polymeric biologic-ligand complexes.

Clinical efficacy of certolizumab pegol in rheumatoid arthritis

In phase 2 studies, subcutaneous injections of increasing doses of certolizumab pegol were well tolerated in patients with active RA with rapid improvement in ACR responses.⁴⁸ In phase 3 studies, the RAPID 1⁴⁹ and RAPID 2⁵⁰ studies evaluated the efficacy and safety of lyophilized and liquid formulations, respectively, of subcutaneous certolizumab pegol (400 mg at weeks 0, 2, and 4 followed by 200 mg or 400 mg every 2 weeks) plus MTX versus placebo plus MTX for 24 weeks in patients with active RA receiving long-term MTX therapy. Among the 982 patients enrolled in RAPID 1, at week 24 the ACR20 response rates using nonresponder imputation for the

certolizumab pegol 200-mg and 400-mg groups were 58.8% and 60.8%, respectively, compared with 13.6% for the placebo group. Differences in ACR20 response rates in certolizumab pegol–treated versus placebo-treated patients were significant at week 1 and were sustained to week 52 ($P < .001$). The trial also showed that the drug improved physical function as early as week 1 and slowed mean radiographic progression from baseline by week 52, with an increase of 0.4 Sharp units in those receiving 200 mg certolizumab pegol and 0.2 Sharp units in those receiving 400 mg, compared with 2.8 Sharp units in placebo-treated patients ($P < .001$). Neither RAPID 1 nor RAPID 2 showed any advantage for 400 mg over 200 mg certolizumab pegol over 52 weeks after induction with 400 mg.

FAST4WARD was a 24-week randomized, double-blind, placebo-controlled study evaluating certolizumab pegol as monotherapy in 220 patients in whom treatment with one or more DMARDs had previously failed.⁵¹ The patients were randomly assigned to receive subcutaneous certolizumab pegol 400 mg ($n = 111$) or placebo ($n = 109$) every 4 weeks. The primary endpoint of achievement of ACR20 criteria at week 24 was reached by 45.5% of the certolizumab-treated group and 9.3% of the placebo-treated group ($P < .001$). Differences between the certolizumab pegol group and the placebo group in the ACR20 response rate were statistically significant as early as week 1 through to week 24 ($P < .001$). Significant improvements in ACR50, ACR components, DAS28(ESR)-3, and all patient-reported outcomes were also observed early in those treated with certolizumab pegol and were sustained throughout the study.

GOLIMUMAB (SIMPONI)

Golimumab was first approved for use in the treatment of RA, PsA, and AS in 2009.

Pharmacology

Golimumab is a fully human monoclonal antibody derived from TNF-immunized transgenic mice engineered to express human IgG. Its molecular characteristics include amino acid sequences that match those of human

germline IgG1, high affinity and neutralization capacity for human TNF- α , conformational stability, and high solubility. Golimumab is dosed every 4 weeks.⁵²

Clinical efficacy of golimumab in rheumatoid arthritis

Golimumab has been studied in both intravenous and subcutaneous formulations but currently is available only for subcutaneous use. Phase 3 RA studies have been reported in three important populations: MTX-naïve patients (GO-BEFORE), patients with active RA despite ongoing treatment with MTX (GO-FORWARD), and patients in whom previous anti-TNF treatment was ineffective (GO-AFTER). Patients receiving subcutaneous injections of golimumab 50 mg or 100 mg every 4 weeks and MTX weekly experienced significant improvements in signs and symptoms and physical function and decrease in disease activity.

In the GO-BEFORE study golimumab was administered once every 4 weeks by subcutaneous injection; MTX-naïve patients with active RA received either golimumab 100 mg alone, golimumab 50 mg or 100 mg in combination with MTX, or MTX alone. When data for three patients who did not receive the study drug but were included in the analysis as nonresponders were included, the primary endpoint, achievement of ACR50 criteria by intent-to-treat analysis, was not reached. However, when data for these three patients who did not receive golimumab were excluded, a modified intent-to-treat analysis showed that the proportion of patients achieving ACR50 criteria was statistically higher in those receiving golimumab 50 mg every 4 weeks plus MTX than in those receiving MTX alone.⁵³

In the GO-FORWARD study, 50-mg and 100-mg doses of golimumab were examined in patients whose disease was active despite ongoing treatment with MTX.⁵⁴ At week 14, 55% of patients receiving golimumab 50 mg plus MTX and 56% receiving golimumab 100 mg plus MTX achieved at least 20% improvement in signs and symptoms of RA (ACR20), compared with 33% of patients receiving placebo and MTX ($P < .01$ and $P < .001$, respectively). Improvements were seen as early as the first clinical assessment, which was 4 weeks after the first golimumab injection, and generally increased over time. At 24 weeks, 68% of patients in the golimumab 50-mg dosing group and 72% of patients receiving golimumab 100 mg experienced clinically relevant improvement in physical function compared with 39% of patients receiving placebo plus MTX ($P < .0001$).

GO-AFTER was the first large phase 3 randomized, double-blind, placebo-controlled trial to test the efficacy of anti-TNF switching in patients in whom the first anti-TNF agent failed.⁵⁵ Four hundred sixty-one patients who had previously received at least one anti-TNF agent, among whom 25% ($n = 115$) had been treated with two therapies and 9% ($n = 43$) with three, were enrolled in this study. Discontinuation of previous anti-TNF therapy was due to lack of efficacy (58%), intolerance (17%), or other reasons (40%). Patients received subcutaneous placebo, golimumab 50 mg, or golimumab 100 mg every 4 weeks. At baseline, 66% of patients were receiving MTX, 5% were receiving sulfasalazine, and 7% were receiving hydroxychloroquine. Among patients who discontinued a previous anti-TNF because of lack of efficacy, 35.7% and 42.7% of patients in the golimumab 50-mg and 100-mg groups, respectively, achieved ACR20 criteria at week 14 compared with 17.7% in the placebo group.

PHARMACOECONOMIC CONSIDERATIONS

Although the addition of TNF inhibitors has significantly impacted the lives of hundreds of thousands of patients worldwide, the addition of these agents to the arsenal of standard antirheumatic therapy has dramatically increased the cost of care in RA. The cost of having a chronic inflammatory disease is often overlooked in these deliberations. For example, in reaching their conclusions about the cost effectiveness of biologic anti-TNFs in the United Kingdom, NICE does not take into account the broader societal implications of the underlying condition such as loss of employment, loss of work productivity, the need for state benefits, and other indirect costs. There is a growing body of data confirming the substantial cost implications of autoimmune rheumatic diseases. For the TNF inhibitors, the notable clinical efficacy observed needs to be factored into a comprehensive assessment of their value. Results from a number of studies have begun to make a compelling case that these agents may have an incremental cost effectiveness within the range of currently accepted medical interventions. Pharmacoeconomic considerations are likely to remain a central factor affecting the use of novel therapies in rheumatology and other specialties. These considerations have led to several recent controlled trials addressing the feasibility of withdrawing TNF inhibitors in patients who achieve disease control. In a Japanese

study population, 9 of 56 patients whose RA was in remission after at least 24 weeks of infliximab therapy maintained remission for 1 year after discontinuation of the biologic; two showed no radiographic progression.⁵⁶ In the Optimal Protocol for Treatment Initiation with MTX and Adalimumab Combination Therapy in Patients with Early Rheumatoid Arthritis (OPTIMA) study, 926 patients with early RA received either MTX or MTX plus adalimumab.⁵⁷ At 24 weeks, patients who achieved low disease activity while receiving combination therapy were randomly reassigned, in a double-blinded manner, to continue the same treatment or withdraw adalimumab. Of those who discontinued adalimumab, 57% reached the composite endpoint of low disease activity with no radiographic progression after an additional year of therapy. Radiographic nonprogression was seen in 89.3% of those who continued adalimumab and 80.6% of those who did not.⁵⁸ In the PRESERVE study (a prospective, randomized etanercept study to evaluate reduced-dose etanercept 25 mg plus MTX versus full-dose etanercept 50 mg plus MTX versus MTX alone in patients with moderate RA), 604 patients received weekly etanercept in addition to background MTX. At 9 months, those with low disease activity either discontinued etanercept, continued etanercept at 50 mg/wk, or received a lower etanercept dose of 25 mg/wk in a double-blind study.⁵⁹ Over the next year, low disease activity was maintained in the majority of those who continued etanercept (82.6% of the 50-mg group, 79.1% of the 25-mg group), but in only 42.6% of those who discontinued etanercept. The mean change in modified total Sharp score was significantly greater in those discontinuing etanercept than in those continuing it (0.06 units/yr at the 50-mg dose, 0.5 units/yr at the 25-mg dose, and 0.6 units/yr without etanercept).

EXPANDED INDICATIONS

TNF- α inhibitors have been approved for use in juvenile arthritis, moderate to severe RA, early RA, PsA, psoriasis, AS, Crohn disease, pediatric Crohn disease, and ulcerative colitis. This approval is particularly important for PsA, spondyloarthritis, and AS (Box 63.4, Table 63.5) in which traditional DMARDs have been proven ineffective or potentially toxic. However, exploratory clinical trial results involving other disorders thought to be TNF mediated (e.g., multiple sclerosis, congestive heart failure, sarcoidosis, anti-neutrophil cytoplasmic antibody (ANCA)-associated granulomatous vasculitis) have generally been disappointing.

Ankylosing spondylitis

TNF inhibitors reproducibly induce substantial improvements in the signs and symptoms of AS and are significantly superior to placebo treatment.⁶⁰ Clinical response, as measured by ASAS20 and BASDAI 50 outcomes, appears comparable for all three agents, and a high-level response, defined as *partial remission*, may be seen. All TNF inhibitors improve spinal mobility measures, with the greatest changes noted in the cervical spine (occiput to wall measurement) and the least noted in the lumbar spine (Schober test).

Nonetheless, all AS patients appear to experience flare on discontinuation of therapy, with the mean time to flare ranging from 6 weeks with etanercept to 17.5 weeks with infliximab. Continuous therapy with TNF

BOX 63.4 INTERNATIONAL ASAS CONSENSUS STATEMENT ON THE USE OF TUMOR NECROSIS FACTOR INHIBITORS IN ANKYLOSING SPONDYLITIS

- Patients should meet modified New York criteria for AS.
- Active disease of longer than 4 weeks. Disease activity is defined as BASDAI greater than 40 (0 to 100).
- All patients should have had adequate therapeutic trials of at least two NSAIDs.
- Patients with pure axial manifestations do not have to take DMARDs before anti-TNF treatment can be started.
- Patients with symptomatic peripheral arthritis should have an insufficient response to at least one local corticosteroid injection if appropriate.
- Patients with persistent peripheral arthritis must have had a therapeutic trial of sulfasalazine.
- Patients with symptomatic enthesitis must have failed appropriate local treatment.

TABLE 63.5 Use of tumor necrosis factor (TNF) inhibition in orphan disorders

TNF inhibitor use: unapproved indications and orphan use	
Large prospective, randomized, controlled trials or meta-analyses	
Benefits shown	Ineffective/equivocal findings
Anterior uveitis	Etanercept in ANCA-associated granulomatous vasculitis Sjögren syndrome
Limited reports of clinical benefits* Uncertain/equivocal benefits reported†	
Reactive/undifferentiated arthritis	Autoimmune inner ear disease
Pustular psoriasis	Sarcoidosis: pulmonary, ocular, resistant
Acrodermatitis continua of Hallopeau	Chronic obstructive pulmonary disease
Psoriatic onychopachydermoperiostitis	Asthma
Pyoderma gangrenosum	Aphthous stomatitis
Pemphigus	Sneddon-Wilkinson disease
SAPHO syndrome	Eosinophilic fasciitis
Hepatitis C virus infection	Panniculitis
Constrictive pericarditis	Eosinophilic fasciitis
Multicentric reticulohistiocytosis	Necrobiosis lipoidica diabetorum
Recurrent ovarian cancer	Hidradenitis suppurativa
Graft-versus-host disease	Idiopathic pulmonary fibrosis
Polyarteritis nodosa	Inclusion body myositis
Takayasu arteritis	Dermatomyositis
Behçet syndrome (ocular more than skin)	Polymyositis
Adult-onset Still disease	Scleroderma
Systemic juvenile idiopathic arthritis	Recalcitrant hand pompholyx
TNF receptor–associated periodic	Myelodysplastic syndrome (TRAPS)
Hyperimmunoglobulinemia D syndrome	Sciatica
PAPA syndrome	Discogenic spinal pain
Orbital myositis	Infertility
Amyloidosis	Endometriosis
ANCA-associated granulomatous vasculitis	Pulmonary tuberculosis
	Systemic lupus erythematosus
*Limited benefit: >1 positive, anecdotal, or uncontrolled report of benefit. †Uncertain/equivocal benefit: single limited and uncontrolled report of benefit or several negative or several conflicting reports. ANCA, antineutrophil cytoplasmic antibody.	

inhibitors will likely be necessary to maintain clinical benefit. TNF inhibitors also improve the quality of life among treated AS patients and may decrease extraarticular inflammatory involvement in some patients. In a systematic review that included data from randomized controlled trials and open-label experience, flares of anterior uveitis occurred less frequently with TNF inhibitor therapy (6.8 per 100 patient-years) compared with placebo (15.6 per 100 patient-years).⁶¹

MRI studies of AS patients treated with TNF inhibitors have shown attenuation of spinal inflammation.⁶⁰ Although suppression of inflammation was maintained for up to 2 years, it was not completely eliminated in most patients. However, TNF blockade does not prevent radiographic ankylosis over 2 years,⁶²⁻⁶⁴ although a recent study suggests that longer-term treatment (8 years) may reduce radiographic progression.⁶⁵ Guidelines for TNF inhibitor use in AS have been developed by an international group of rheumatologists (see Box 63.4).

Psoriatic arthritis

TNF inhibitors are effective in treating both the skin and joint disease (peripheral and spinal) in PsA. TNF inhibitor therapy also improves functional status, quality of life, dactylitis, and enthesitis,^{60,66,67} and diminishes the progression of radiographic peripheral joint disease in PsA.⁶⁰

Although improvement in cutaneous disease was seen in most trials of TNF inhibitor in PsA, these patients often had less baseline cutaneous

involvement (as measured by the Psoriasis Activity Severity Index) compared with those in the psoriasis trials. Although all TNF inhibitors tested ameliorate cutaneous disease and peripheral arthritis, the magnitude of improvement in skin disease appears to be greater with the monoclonal antibodies (infliximab, golimumab, and adalimumab) than with the soluble receptor construct (etanercept). Whether this difference relates to dosing, different mechanisms of action, or other factors, remains to be defined.

Other orphan disorders

The use of TNF inhibitors has rapidly spread to a growing list of uncommonly encountered inflammatory disorders (see Table 63.5). Reports of their usefulness in these “orphan” disorders are limited to investigator-initiated, single-center, open-label, and uncontrolled trials with few treated patients. Many of these reports have been presented only in abstract form and had not appeared in peer-reviewed publications. Moreover, assessment of outcomes suffers from the lack of standardized and validated measures. Table 63.5 lists those conditions in which TNF blockade has been attempted, has succeeded, or has failed.

Granulomatous disease

TNF-α plays a pivotal role in granuloma formation and stabilization, by promoting the differentiation of epithelioid macrophages to form granulomas capable of sequestering infected cells. For these reasons, anti-TNF therapy was postulated to be effective in diseases characterized by granulomatous inflammation. Although early uncontrolled reports have shown some therapeutic success in these disorders, subsequent research has undermined these as potential indications.

Antineutrophil cytoplasmic antibody–associated granulomatous vasculitis

Uncontrolled exploratory trials have shown that the addition of infliximab or etanercept lowers Birmingham Vasculitis Activity Scores or induces remission in granulomatous vasculitis.⁶⁸ Nonetheless, the efficacy of anti-TNF therapy in ANCA-associated granulomatous vasculitis was questioned when a large (n = 180 patients), 9-month trial of etanercept versus placebo in patients with active ANCA-associated granulomatous vasculitis failed to show any benefit of adding etanercept to background therapy and was associated with an increased number of malignancies compared with placebo treatment.^{69,70}

Giant cell arteritis

Despite anecdotal case reports of benefit of TNF inhibition in giant cell arteritis,⁷¹ an interim analysis of data from a controlled trial failed to show any benefit in 44 corticosteroid-treated patients who received either infliximab (5 mg/kg) or placebo. Relapse rates and rates of steroid reduction were the same in both groups after 54 weeks of observation.⁷²

Polymyalgia rheumatica

Open-label reports have suggested that infliximab may be effective in polymyalgia rheumatica. However, a 22-week placebo-controlled trial involving 51 consecutively treated patients with polymyalgia rheumatica failed to show any benefit of infliximab over placebo.⁷³

Sarcoidosis

Anecdotal reports suggested the efficacy of infliximab, etanercept, and adalimumab in sarcoidosis.⁷⁴⁻⁷⁶ Most patients showing a response were treated with infliximab and had extrapulmonary manifestations of sarcoidosis (skin [lupus pernio], ocular [uveitis], joint, or bone). A small, placebo-controlled trial in patients with ocular sarcoid failed to show any benefit of infliximab over placebo.⁷⁷ A 30-patient, prospective, open-label trial of etanercept in stage II pulmonary sarcoid produced negative results.⁷⁸ A large placebo-controlled trial showed modest but significant improvement in chronic pulmonary sarcoidosis patients treated with infliximab.⁷⁹

Pyoderma gangrenosum

Rapid resolution^{79a} of pyoderma gangrenosum lesions using single or multiple doses of infliximab 5 mg/kg (given at weeks 0, 2, and 6) has been observed. Continued therapy and occasional dose escalation were necessary to maintain control or remission in some of these patients.

Takayasu arteritis

There are limited reports of favorable outcomes when TNF blockade is used to treat Takayasu arteritis, a large vessel vasculitis. Open-label uncontrolled studies claimed efficacy in patients who had active disease despite

treatment with corticosteroids and MTX. All uniformly claimed amelioration of disease and a corticosteroid-sparing effect. Limited numbers and potential positive reporting bias should temper enthusiasm until controlled trials are done.

Inflammatory eye disease/uveitis

In juvenile arthritis and spondyloarthritis, joint indices responded well to anti-TNF therapy but variable ocular benefits were seen. A meta-analysis of AS trials using TNF inhibitors studied the pretreatment prevalence and posttreatment flares of anterior uveitis.⁶¹ The frequency of uveitis flares was 15.6 per 100 patient-years in placebo-treated patients and 6.8 per 100 patient-years in those receiving etanercept or infliximab. Nonetheless, these trials recorded several instances of new-onset anterior uveitis in patients while receiving etanercept or infliximab. Uncontrolled reports have claimed TNF inhibition also to be effective in the management of noninfectious refractory posterior uveitis.

Behçet syndrome

Anecdotal reports of the use of TNF inhibitors (primarily infliximab) in Behçet syndrome have suggested therapeutic benefits in difficult cases. In a 40-patient, placebo-controlled, 4-week trial, etanercept lessened the frequency of mucocutaneous manifestations in patients with Behçet syndrome.⁸⁰

Sjögren syndrome

A double-blind, randomized, placebo-controlled trial of infliximab failed to show any improvement in dryness, joint pain, fatigue, salivary flow rate, Schirmer test results, or CRP levels in patients with Sjögren syndrome.⁸¹ Similar negative results were seen in a placebo-controlled study of etanercept use in Sjögren syndrome patients.⁸² These data suggest that TNF inhibition is not an effective treatment for Sjögren syndrome.

Chronic lung disease

There have been uncontrolled reports of TNF blockade in patients with interstitial pneumonitis, but a placebo-controlled study failed to demonstrate efficacy in patients with chronic obstructive pulmonary disease (COPD) treated with infliximab.⁸³ TNF blockade in refractory asthma is not efficacious.^{84,85} There are rare reports of new-onset asthmatic flares, pulmonary infiltrates, granulomas, and fibrosing alveolitis in patients receiving etanercept, infliximab, or adalimumab.

Hepatitis B and C

Elevated TNF levels have been demonstrated in patients with hepatitis C. Hence a pathogenic role for TNF in hepatitis C virus (HCV) infection has been suggested but not clarified. Retrospective, open-label, prospective studies have not demonstrated worsening of hepatic enzyme levels or viral load titers with TNF inhibition. The potential adjuvant effect of etanercept therapy, combined with interferon and ribavirin, was studied in 50 nonarthritic patients with chronic HCV infection.⁸⁶ This 6-month, double-blind, placebo-controlled trial showed lower viral loads, normal hepatic enzyme levels, and fewer adverse events when etanercept was combined with this antiviral regimen. These data suggest that TNF inhibition may be used cautiously in HCV-infected patients with markedly limited treatment alternatives.

A rise in reports of hepatitis B virus (HBV) reactivation following TNF inhibition has led to the recommendation that patients be screened for HBV infection before use of anti-TNF therapy. For hepatitis B surface antigen (HBsAg) carriers, either anti-HBV treatment or prophylaxis is mandatory before anti-TNF therapy to prevent hepatitis reactivation. By contrast, TNF inhibition can be used with caution in HBsAg-negative patients who are nonetheless seropositive for antibodies to hepatitis B core antigen, although careful monitoring is recommended.⁸⁷

BASELESS USE OF TUMOR NECROSIS FACTOR INHIBITORS

The popularity of TNF blockade has often led to its application in a variety of conditions presumed to have an underlying inflammatory or immune-mediated pathogenesis. Table 63.5 lists many conditions for which the benefits of TNF inhibition are uncertain and unproven.

p55 TUMOR NECROSIS FACTOR INHIBITORS

Three different p55-directed TNF inhibitors have been studied but none is currently approved or actively under investigation for inflammatory indications. Onercept is a recombinant monomeric soluble TNFR1 (p55), lenercept is a recombinant fusion protein with two p55 soluble TNFRs fused to the Fc portion of IgG1, and pegsunercept is a recombinant monomeric p55 soluble TNFR with PEG linked to enhance its half-life. Reasons for the deferment of development of these p55 inhibitors are unclear but may relate to clinical trial results, toxicity concerns, or pharmacokinetic issues.

Tumor necrosis factor inhibitors in early rheumatoid arthritis

Numerous studies have confirmed the efficacy and safety of TNF inhibition in patients with new-onset RA^{23,31,42} and have led to FDA approval for use (as the initial DMARD) in patients with new-onset RA. Although entry into these early RA trials was limited to patients with a disease duration of less than 3 years, patients had a mean duration of disease of 6 to 12 months. Hence several large, randomized, controlled trials in early RA (ERA, ASPIRE, PREMIER, GO-BEFORE, BeST) have taught us that (1) ACR20 responses with TNF inhibitors are equivalent to, or in some cases better than, those with MTX; (2) the best responses (DAS remission, ACR70 response) are achieved when TNF inhibitors are combined with MTX; (3) TNF inhibitors are superior to MTX in halting radiographic progression (especially when combined with MTX); and (4) the safety of TNF inhibition in early RA appears to be equal to, or better than, that seen in established or severe RA. Due to cost issues it is generally accepted that patients with new-onset RA should initially receive MTX as their primary DMARD. TNF inhibition should be employed early when MTX cannot be used and/or when the patient is at high risk of severe RA or when patients are not fully responsive to MTX therapy.

Tumor necrosis factor inhibitors in children

The use of TNF inhibition in children with juvenile arthritis has been limited by the availability of few studies. Currently, only etanercept is approved for use in patients with active polyarticular juvenile arthritis after an inadequate response to MTX or other DMARD therapy. The safety and efficacy of etanercept was studied in 69 patients with polyarticular juvenile arthritis unresponsive to MTX.⁸⁸ Patients (4 to 17 years of age) received 0.4 mg/kg twice weekly for 90 days and showed a 74% response rate. After 90 days, patients who showed a response were randomly assigned to receive placebo or etanercept for 4 months and flare rates were assessed. The time to flare was much shorter for placebo-treated patients (28 days) than for those receiving etanercept (more than 116 days).

Tumor necrosis factor inhibitors in the elderly

Drug development pharmacokinetic studies of etanercept, infliximab, and adalimumab failed to show any influence of age or gender. During infliximab clinical trials in RA, efficacy and safety in 181 geriatric patients (older than 65 years) were similar to those in younger patients; however, both older infliximab-treated patients and older control patients exhibited more serious adverse events than did younger patients. Etanercept has been studied in older patients with RA and PsA in clinical trials demonstrating no difference in efficacy or safety between elderly and younger patients.

Because advancing age appears to be a risk factor for serious infection, TNF inhibitors should be used with caution in geriatric patients, especially those with comorbidities, debility, and a history of serious infection.

SAFETY OF ANTI-TUMOR NECROSIS FACTOR THERAPY

Advances in treatment afforded by TNF blockade have been tempered by safety concerns, many of which were reported in the controlled clinical trials. These clinical trials established the most common adverse events among thousands of patients who were selected because they had few or no comorbidities and met limitations on age, disease status, and background therapies. Identifying a real-world spectrum of TNF inhibitor-related safety concerns depends on a variety of pharmacovigilance efforts (e.g., open-label extension trials, phase 4 trials, postmarketing surveillance, passive physician and patient reports, disease databases and registries) involving less select populations with comorbidities and variable drug dosing and

background medications. In the postmarketing era, information on the safety of TNF inhibitors has accumulated with more than 15 years of experience and over 2 million patients treated worldwide. Although pharmacovigilance data may be limited by event underreporting, unverified diagnoses, duplicate reports, confounding comorbidities or medications, and uncertain temporal associations or causality, they offer our most comprehensive view of TNF inhibitor safety.

Box 63.3 details the relative contraindications to the use of TNF inhibitors. Moreover, the use of these agents in unapproved, rare, or orphan conditions may be associated with unexpected or unsatisfactory outcomes. Although many safety issues (e.g., the occurrence of tuberculosis, opportunistic infection, lupus) might have been predicted on the basis of preclinical studies, the development of unanticipated adverse events in newly exposed patient populations (e.g., demyelinating disease, heart failure, cytopenia) should temper inappropriate and widespread use of TNF inhibitors.

One indication of both efficacy and safety is the durability of an agent (e.g., how long a patient continues to receive such therapy). In randomized, placebo-controlled clinical trials, patients receiving TNF inhibitors consistently demonstrated higher study completion rates and lower dropout rates than those for placebo-treated or matched controls. Real-world observational studies have shown that the durability of the TNF inhibitors compares favorably with that of MTX, so that 65% to 80% of RA patients are still taking their TNF inhibitors 1 year after drug initiation.^{22,89} Dropouts for safety account for approximately 30% to 50% of those who discontinue TNF inhibitor therapy. Several studies consistently show the dropout rate for these agents to be nearly 10% to 15% per year in the first 2 years and roughly 10% per annum thereafter.

Infusion reactions

Infusion reactions to these parenterally administered agents are among the most common of adverse effects. Clinical trials reported that up to 20% of infliximab-treated patients experience an infusion reaction. However, fewer than 1% of infliximab-treated patients develop a serious infusion-related reaction, and only 2.5% of reactions are the cause of drug cessation. Most infliximab infusion reactions occur during infusion or within 2 hours after infusion. Common complaints include headache (20%), nausea (15%), urticaria, pruritus, rash, flushing, fever, chills, tachycardia, and dyspnea. In many, infusion reactions may be the result of a rapid infusion rate. The infusion reactions are usually transient, are rarely severe, and typically can be controlled by slowing the rate of infusion or treating with acetaminophen, nonsedating antihistamines, or short-acting corticosteroids. Premedication with the aforementioned agents is not routinely required but may be necessary in those who exhibit infusion reactions.

Rarely, severe or anaphylactic reactions occur in which findings of chest tightness, bronchospasm, hypotension, diaphoresis, anaphylaxis, or a feeling of impending doom may occur. In these individuals, infliximab therapy should be halted and supportive or emergent care administered until the patient's condition is stabilized. For these reasons infliximab infusions should be delivered only with appropriately trained medical personnel in attendance and with ready access to parenteral corticosteroids, diphenhydramine, and epinephrine.

Infusion reactions are twofold to threefold more likely if HACA are present. The immunogenicity of infliximab can be mitigated by concomitant MTX use or administration of higher infliximab doses. Experience with intermittent treatment of Crohn disease has shown reactions to be more likely when infliximab therapy is intermittent and suspended. In these patients, 25% developed delayed reactions (3 to 12 days after infusion) with symptoms of myalgia, arthralgia, fever, chills, rash, urticaria, edema, dysphagia, and sore throat.

Injection site reactions

During the RA adalimumab and etanercept clinical trials, cutaneous injection site reactions were seen in 20% and 37% of patients, respectively. However, these are less frequent in practice and rarely require drug discontinuation. Injection site reactions are usually mild or moderate and resolve within 7 days. They are most common during the first 4 to 8 weeks of use and do not correlate with drug dose, frequency of administration, or the presence of neutralizing antibodies. Patients may describe dysesthesia, bruising, erythema, pruritus, or urticaria at administration sites. Interestingly, in the TEMPO (etanercept) trial, fewer injection site reactions were observed in the MTX plus TNF inhibitor group than in those receiving the TNF inhibitor alone.³³ In the placebo-controlled trials of certolizumab, 6.4% of patients treated with certolizumab developed injection site reactions, compared with 6.5% of patients receiving placebo. In golimumab phase 3

trials through week 16 in RA, PsA, and AS, 5.8% of golimumab-treated patients had injection site reactions compared with 2.2% of control patients. In both the certolizumab and golimumab trials, the incidence of injection site pain was low at 1.5% or fewer patients, with no cases leading to withdrawal.

Infectious risk

In otherwise healthy individuals, TNF plays an important role in defense against infections, especially infection with intracellular organisms. In the context of infection, TNF enhances endothelial cell activation at the site of involvement, promotes inflammatory cell recruitment, and has a procoagulant role in limiting the spread of infection. It also increases the ability of activated macrophages to phagocytose and kill mycobacteria. Concerns that modulation of physiologic or excess TNF levels by specific inhibitors might promote infectious complications were heightened because of animal studies demonstrating the fatal effects of TNF inhibition in models of sepsis or endotoxic shock and the protective role of TNF with respect to opportunistic infections such as those caused by *Mycobacterium tuberculosis*, *Candida*, *Histoplasma*, *Leishmania*, and malarial organisms. Several early trials of TNF inhibition as a therapy for sepsis failed to show any consistent benefit or hazard to TNF neutralization.

RA patients have approximately twice the mortality rate of the general population, and serious infection (leading to hospital admission, intravenous antibiotic administration, or death) is a major contributing factor. In considering whether anti-TNF biologics raise infection risks, the higher background infection rates in RA need to be taken into account. Similarly, the influence of concomitantly administered drugs must also be considered. For example, a review of data from a large patient registry in the United States encompassing over 16,000 patients observed the risk of pneumonia requiring hospitalization to be 1.7 times higher in patients receiving corticosteroids.⁹⁰ Prednisolone at dosages of only 5 mg/day or less gave a hazard ratio of 1.4 (95% confidence interval [CI], 1.1 to 1.6).

Controlled trials have produced conflicting data with respect to the risk of serious infectious complications, and it must be remembered that registration clinical trials systematically exclude patients with significant comorbidities, so that the results may not be generalizable to RA patients as a whole. In the etanercept, infliximab, and adalimumab clinical trials, common nonserious infections (e.g., upper respiratory tract infections, bronchitis, sinusitis, pharyngitis, urinary tract infections) were seen in 20% to 37% of patients. Anti-TNF therapy was not suspended or stopped for these nonserious infections and patients responded well to either observation or symptomatic therapy.

Serious infectious events (e.g., pneumonia, cellulitis, joint infections) or death from infection were infrequently reported in the clinical trials before FDA approval and, overall, were not observed at a rate greater than that seen in placebo-treated controls. In the randomized placebo-controlled trials of all three TNF target agents (encompassing 6303 patients followed for 6 to 12 months), the rate of serious infectious events ranged from three to four events per 100 patient-years of therapy compared with two events per 100 patient-years in placebo-treated patients. Although many trials have shown no increase in serious infections (compared with placebo or active controls), several trials have shown higher rates of serious infections. For example, serious infections in the ATTRACT and ASPIRE trials were seen in 5.4% of infliximab/MTX-treated patients and 3.4% of patients treated with MTX alone.³⁹⁻⁴² Pneumonia was seen in 1.7% of infliximab-treated and 0.3% of placebo-treated patients (Table 63.6). Similarly, the DE019 trial found more serious infections in the adalimumab/MTX group (3.8%) compared with the MTX/placebo group (0.5%).²⁵ The PREMIER trial reported different serious infection rates in patients treated with MTX, adalimumab, and the combination of MTX/adalimumab (1.6, 0.7, and 2.9 events per 100 patient-years, respectively).²³ Postmarketing studies have also shown mixed results, with either equal or increased infection rates for TNF inhibitors compared with DMARD controls.⁹¹⁻⁹³ Reported serious infections include pneumonia, cellulitis, septic arthritis, prosthetic joint infections, postsurgical or wound infection, diverticulitis, pyelonephritis, abscess, and sepsis.

A meta-analysis of selected clinical trials of infliximab, etanercept, and adalimumab reported a pooled odds ratio of 2.0 for serious infections in patients taking anti-TNF antibodies compared with the control groups.⁹² As in the case of controlled trials, observational studies have produced conflicting data with respect to the risk of serious infectious complications with TNF inhibitors, with some studies suggesting increased serious infection rates and others no difference compared with groups not given TNF inhibitors. These apparent discrepancies may be due to many factors, including the variation in background rate of infection in different populations and locations, the duration of exposure to TNF inhibition,^{93,94} confounding

TABLE 63.6**Frequency of serious adverse events with the tumor necrosis factor (TNF) inhibitors infliximab, etanercept, and adalimumab**

concomitant therapy, and differences in disease severity between anti-TNF-treated and comparison cohorts. Another factor may relate to the biology of TNF inhibition. Evidence suggests that normalization of immune disequilibrium in RA may restore physiologic immune responses. For example, infliximab treatment in RA results in significant increases in circulating regulatory T cells and reversal of their anergic phenotype.⁹⁵ Thus it is possible that patients with well-controlled inflammation become less susceptible to infection than those with partially controlled inflammation or oversuppression of TNF.⁹⁶

A review of infectious risk data emerging from observational studies and the various national registries might suggest a variable level of risk. But when the incidence rate ratios are plotted against the duration of follow-up, a clear and consistent pattern emerges suggesting that risk of infectious complications is highest during the initial period of exposure to an anti-TNF and tends to decline after 6 months of therapy.⁹⁴ In patients enrolled into the German biologics register RABBIT (etanercept, *n* = 512; infliximab, *n* = 346; DMARD control, *n* = 601), the reported relative risk of serious infections was 2.2 (95% CI, 0.9 to 5.4) for etanercept (64 per 1000 patient-years) and 2.1 (95% CI, 0.8 to 5.5) for infliximab (62 per 1000 patient-years) compared with patients taking DMARDs only (23 per 1000 patient-years).⁹⁷ Despite the lower confidence intervals overlapping with 1.0, these findings suggest a trend toward increased risk of serious infection. This risk was independent of RA severity or duration, rheumatoid factor seropositivity, concomitant steroid use, diabetes, and lung disease.

A retrospective U.S. study encompassing 3894 person-years of anti-TNF therapy and 4846 person-years of MTX therapy over a median of 17 months reported the adjusted risk of hospitalization caused by bacterial infection, which was 1.9-fold higher in patients receiving anti-TNF agents (4.2-fold higher in the first 6 months).⁹⁸ The Spanish registry showed a 1.6-fold increase in the rate of serious infection with TNF inhibition in an analysis of 2868 patient-years of anti-TNF drug therapy compared with 2433 patient-years of controls.⁹⁹ A case-control cohort study of 23,733 RA patients suggested a twofold increase in risk of all infections in patients taking TNF blockers (infliximab and etanercept).¹⁰⁰ However, because of the limited number of patients receiving anti-TNF therapy (*n* = 261), the confidence interval was wide. Another retrospective study of 709 RA patients reported an incidence of serious infections of 3.4 per 100 patient-years before anti-TNF treatment and 10.5 afterward treatment.¹⁰¹ A meta-analysis of observational studies that restricted inclusion to studies reporting adjusted incidence rate ratios reported the pooled adjusted risk from five cohort studies and two case-control studies to be 1.37 (95% CI, 1.18 to 1.60).¹⁰²

The British Society for Rheumatology Biologics Register (BSRBR) reported the observations of a national prospective observational study of 7664 RA patients treated with anti-TNF agents and 1354 treated with DMARDs. No increase in serious infections in total was observed in anti-TNF-treated patients compared with patients given conventional DMARDs.¹⁰³ The incidence of serious infections in the anti-TNF group was 53.2 per 1000 person-years versus 41.2 in the control group. However,

serious skin and soft tissue infections were more frequent in anti-TNF-treated patients (incidence risk ratio, 4.2). A total of 19 serious bacterial intracellular infections occurred, all in patients in the anti-TNF-treated cohort. An extended analysis found an increased adjusted incidence rate of serious infection (ratio, 4.6; 95% CI, 1.8 to 11.9) over the first 90 days after starting anti-TNF drugs compared with DMARD therapy.⁹³

Another study followed 686 patients for 52 weeks and found no difference in the prevalence of serious infections in those receiving MTX and etanercept in combination compared with those receiving either drug alone (about 4% for all groups).¹⁰⁴ In a large cohort of 16,788 patients followed over 3.5 years, no increase in pneumonia risk with anti-TNF treatment was observed.⁹⁰ In a retrospective study involving patients older than 65 years of age, 1900 patients receiving MTX and 469 receiving anti-TNF drugs were followed for 0.2 to 1.3 years,¹⁰⁵ and no increase in infection rate in the anti-TNF group was found.

Despite apparently contradictory findings with respect to the risk of infectious complications of anti-TNF therapy based on observational studies and registry data, a more detailed analysis of available data suggests a more coherent pattern of an increased risk shortly after treatment starts.⁹⁴ Importantly, an analysis of RABBIT data found that this apparent reduction of risk over time was due in part to the removal of patients at risk of infection from the exposed cohort.¹⁰⁶

Current prescribing guidelines caution against the use of TNF inhibitors in patients with active serious infections or in those with chronic or recurrent infections, and patients should be monitored for signs and symptoms of infection while receiving TNF inhibitors. Even in patients with severe rheumatoid disease activity, there may be a point at which infection risks associated with TNF blockade outweigh any potential benefits. Moreover, the infectious risk may be heightened in the presence of well-known risk factors, such as advanced age, debility, extreme inflammatory activity, corticosteroid use (especially at higher dosages), comorbidities, skin breakdown, and planned major surgery (e.g., joint replacement). Increasing data suggest that higher dosages of TNF inhibitors may also increase the risk of infection.^{39,96} Serious bacterial infections may therefore be averted by proper patient selection, proper dosing, and TNF inhibitor avoidance if numerous risk factors for infection are present. Lastly, the combination of anakinra and a TNF inhibitor should be avoided because both open-label and controlled trials showed no clinical benefit but demonstrated an increased risk of serious infections (7% and neutropenia (2%)).¹⁰⁷ Similarly, abatacept (CTLA-4-immunoglobulin) should not be combined with TNF inhibitor therapy because this combination also yielded higher rates of serious infections (5.8% vs. 1.9%) in a randomized clinical trial.¹⁰⁸

Guidelines for the prevention and management of infections, especially serious infections, are currently lacking. Patients experiencing mild to moderate upper respiratory tract infection, bronchitis, or sinusitis can be symptomatically managed or closely observed without drug cessation. However, patients demonstrating high fevers or other suspicious symptoms should undergo temporary drug suspension and further evaluation. TNF inhibitors should be stopped when patients have a serious infection, hospitalizable infection, or opportunistic infection and should not be restarted until adequate control has been achieved. Patients undergoing elective major surgery (e.g., joint replacement surgery) may also benefit from suspension of the TNF inhibitor before surgery for at least one dosing cycle (e.g., 7 days for etanercept, 14 days for adalimumab, 6 to 8 weeks for infliximab), provided such cessation does not induce a major inflammatory flare, but this suggestion is not evidence based because of the limited number of studies in this area. Although one study showed that RA patients receiving TNF inhibitors had a fivefold increased risk of serious infection after joint arthroplasty,¹⁰⁹ further research is necessary to determine how best to manage these patients.

Tuberculosis

TNF antagonist therapy can interfere with the host's ability to protect itself from mycobacterial infection. TNF plays an important role in the formation and maintenance of granulomas. Tuberculosis (TB) and other opportunistic infections have been associated with all currently marketed TNF blocking agents. Hence therapeutic inhibition of TNF augments the risk of reactivation of latent mycobacterial (or fungal) infection. Interestingly, 30% to 50% of such patients have extrapulmonary, miliary, or disseminated and nonpulmonary presentations of TB. Although the risk of TB is increased in all patients receiving TNF inhibitors, even greater rates are seen in populations from geographic regions in which TB is endemic.¹¹⁰ All sources that have compared the risk of TB in anti-TNF-exposed patients with that in a reference rheumatoid population have found increased risk. There is clear evidence from the BIOBADASER database that application of TB screening guidelines significantly reduced that risk. Nonetheless, the risk across

various observational cohorts is increased 2.4- to 8.7-fold compared with nonexposed RA patients.¹¹⁰⁻¹¹²

Although no cases of TB emerged in the etanercept clinical trials, post-marketing analyses demonstrated 38 confirmed cases of etanercept-associated TB worldwide in the first 150,000 patients treated through December 2002. For infliximab, 441 cases of infliximab-related TB were reported among 492,874 treated patients worldwide, whereas there were only 6 infliximab-related TB cases reported in the clinical trials. Ninety-seven percent of the infliximab-related cases occurred within 7 months of treatment initiation, with a median time to onset of 12 weeks. The incidence of TB in clinical trials of adalimumab was higher in early clinical trials when the dose of adalimumab was higher and no screening procedures were used or enforced. The incidence of TB dropped 85% when adalimumab dose was reduced and screening measures for latent TB infection (purified protein derivative tuberculin [PPD] test, chest radiograph) were required before therapy. In one study, RATIO, the odds ratios for TB reactivation relative to that for etanercept were 13.3 (95% CI, 2.6 to 69.0) for infliximab and 17.1 (95% CI, 3.6 to 80.6) for adalimumab.¹¹³ In the BSRBR study, incidence rate ratios of TB for infliximab and adalimumab compared with etanercept were 3.1 (95% CI, 1.0 to 9.5) and 4.2 (95% CI, 1.4 to 12.4), respectively.¹¹²

The increased risk and extrapulmonary presentations of TB with TNF blockade mandate screening, close follow-up, and ongoing clinical suspicion. The risk of development of TB with TNF antagonist use is significantly reduced with screening and appropriate monitoring. Two different data sets have shown the preventive value of screening before drug initiation. In the adalimumab clinical trials, a TB infection rate of 1.3 per 100 patient-years was decreased to less than 0.11 per 100 patient-years with mandated screening (PPD test in North America and chest radiographs in Europe). A Spanish study reported a reduction of nearly 80% in active TB cases once screening and treatment of latent TB was implemented.¹¹⁰

Current guidelines from the Centers for Disease Control and Prevention (CDC) and the American Thoracic Society recommend PPD skin testing before initiation of TNF antagonist therapy. Physicians who prescribe any TNF antagonist therapy should educate their patients about the symptoms of TB.

The reaction to the tuberculin (PPD) skin test must be read within 48 to 72 hours by a health care professional and is considered positive if induration is greater than 5 mm. Patients previously vaccinated with bacille Calmette-Guérin (BCG) should also be screened with a tuberculin skin test. The use of controls is not recommended because up to one third of RA patients may be anergic. Chest radiography is not routinely performed but should be done in those with a positive tuberculin skin test result, recent or past exposure to TB, signs or symptoms of TB, or history of travel to high-risk endemic areas.¹¹⁴ If results of the PPD test are positive and the patient is without signs, symptoms, or chest radiographic evidence of active infection, treatment for latent TB should commence before or with anti-TNF therapy. CDC guidelines suggest that 9 months of isoniazid therapy are optimal, although 6 months of isoniazid or other alternative regimens also have proven efficacy.

The PPD test is of limited benefit in immunosuppressed individuals, who often fail to mount a delayed-type hypersensitivity reaction. In such patients, newer interferon- γ -releasing assays may be a more robust method for diagnosis of tuberculosis and assessment of latent TB.¹¹⁵ These interferon-releasing assays are not confounded by prior BCG vaccination or exposure to environmental mycobacteria. However, it should be noted that a negative test result does not exclude infection with nontuberculous mycobacteria species, which are usually considered benign contaminants but are nonetheless increasingly recognized to be associated with pulmonary disease in immunocompromised hosts (see Chapter 67).

Other opportunist infections

Patients taking TNF inhibitors should be considered at risk for opportunistic infections, including infection with atypical mycobacteria, *Mycobacterium avium intracellulare*, *Mycobacterium kansasii*, and *Mycobacterium marinum*. Fungal and other opportunistic infections, including histoplasmosis, pneumocystosis, aspergillosis, coccidioidomycosis, sporotrichosis, nocardiosis, listeriosis, and cytomegalovirus infection, have been observed with all TNF inhibitors. Because no reliable skin or serologic testing exists to screen for these infections, clinicians must closely monitor patients for symptoms or signs of opportunistic infections, especially in endemic regions (e.g., Europe, South America, Ohio River Valley, San Joaquin Valley). It should be noted that long-term prednisone therapy may also predispose to such infections.

Immunity against viral infections has some similarity with that against intracellular bacterial infections. An increased risk of herpes zoster

associated with TNF inhibition was noted in the RABBIT registry; the increased risk of severe herpes zoster was seen with the monoclonal antibodies but not with etanercept.¹¹⁶

Neoplasia and lymphoma

Numerous population-based studies have generally shown that RA patients have an increased risk of lymphoma but are not at increased risk of other malignancies (e.g., solid tumors) and may in fact be at a lower risk of adenocarcinoma of the colon, presumably because of the use of nonsteroidal antiinflammatory drugs or cyclooxygenase-2 inhibitors. An overall twofold to threefold increase in lymphoma (primarily non-Hodgkin) has been shown in RA population studies. The lymphoma risk appears to increase with age and increasing inflammatory disease activity. In a 2003 FDA analysis of this issue, six lymphomas were found among 6303 RA patients treated with TNF inhibitors in controlled clinical trials, but none was observed in placebo-treated patients. A total of 23 lymphomas were observed during drug development (9 with etanercept, 4 with infliximab, 10 with adalimumab), which yielded an increased standardized incidence ratio (relative risk) of 3.47, 6.35, and 5.42, respectively. However, the 95% confidence intervals for these standardized incidence ratios were particularly wide and overlapping, so that it was not possible to separate lymphoma risk related to drug use from that associated with active RA alone.

Thus lymphoma rates in RA patients taking TNF inhibitors are elevated, but, as judged by data reported from two sources, ARTIS¹¹⁷ and the NDBRD,¹¹⁸ there is no evidence that the risk of lymphoma is increased in patients taking TNF inhibitors compared with that in RA patients treated with classical DMARDs, since the point estimate was 1.16, although the 95% confidence interval was from 0.72 to 1.60, so a small effect cannot be excluded.¹¹⁹ Data from safety registries suggest that it is disease activity rather than TNF inhibition that may account for the observed increase in lymphoma rates associated with TNF blockade.^{120,121} However, there are reports indicating an increased lymphoma risk related to anti-TNF treatment.¹²² The lag time from TNF blocker exposure to the onset of lymphoma varied, but most cases occurred after 6 to 24 months of TNF therapy. Hodgkin lymphoma occurred in 15%; the remainder were non-Hodgkin lymphomas, usually of the diffuse, large, B-cell class. Follicular, mantle, MALT, and T-cell lymphomas were uncommonly observed.²⁴ These issues merit continued scrutiny in long-term population-based surveillance registries of RA patients receiving biologic and nonbiologic DMARD therapy to provide a clearer understanding of the risk of lymphoma. There have been reports of rare and fatal hepatosplenic T-cell lymphoma in pediatric Crohn disease patients receiving infliximab and generally azathioprine or 6-mercaptopurine. These malignancies have not been observed with adalimumab or etanercept.

In registry studies, no overall increase in malignancy risk has been reported in RA patients whether or not exposed to TNF inhibitors.¹²³ In a recent systematic literature review and meta-analysis, the pooled estimate for the risk of malignancy from six studies was 0.94 (95% CI, 0.84 to 1.05). There was no evidence that longer duration of exposure to TNF inhibitors increased the risk of malignancy. In patients with prior malignancies, there was a higher risk of a new or recurring malignancy, but this risk was not increased further by exposure to TNF inhibitors.¹¹⁹ However, another meta-analysis of studies of patients taking TNF inhibitors (limited to the monoclonal antibodies) showed more malignancies (0.8%) compared with the placebo-matched population (0.2%), with a pooled odds ratio of 3.3 compared with placebo-treated patients. The risks appear to be dose dependent, with those receiving high-dose therapy (defined as 6 mg/kg infliximab or more every 8 weeks or 40 mg adalimumab or more every other week) having the greatest risk (odds ratio, 4.3; 95% CI, 1.6 to 11.8); no important increased risk was seen below these dosages.⁹² The lower than expected rate of neoplasia in the placebo group has been questioned and may relate to the inaccuracies arising from a shorter duration of placebo and TNF inhibitor exposure. There have been other studies demonstrating a higher rate of solid tumors. A 9-month, 180-patient trial examining the use of etanercept in ANCA-associated granulomatous vasculitis revealed six solid tumors in the etanercept group and none in the placebo group.⁶⁹ All six of these patients had received cyclophosphamide, so it may be that the addition of cyclophosphamide to etanercept increases the risk of malignancy. Additionally, a trial of infliximab in patients with severe COPD demonstrated an excess of solid tumors among patients receiving the TNF inhibitor. These analyses suggest that rates of solid tumors may be increased in certain at-risk populations.

Results from several studies concur that patients treated with TNF inhibitors have a significantly increased risk of developing a nonmelanoma skin cancer (relative risk, 1.45; 95% CI, 1.15 to 1.85). Additionally, patients are at increased risk of developing melanoma, because the pooled estimate from

two studies was 1.79 (95% CI, 1.18 to 2.64). Many rheumatologists are now recommending annual skin evaluations for patients receiving anti-TNF therapy. The pooled estimate for the risk of lymphoma was 1.11 (95% CI, 0.70 to 1.61).¹¹⁹

Antibiologic antibody responses

Biologic anti-TNF agents are large foreign proteins and as such are potentially immunogenic, even when the primary amino acid sequence is fully human. The clinical relevance of antidrug antibodies has been controversial, but nonetheless their occurrence might be anticipated to reduce response to treatment, either by inhibiting the functional part of the molecule or by accelerating drug clearance owing to the formation of immune complexes, which might also give rise to hypersensitivity reactions. Approximately 3% of etanercept-treated patients develop antibodies to etanercept. In one study, antibodies to infliximab developed in 53%, 21%, and 7% of patients receiving 1, 3, or 10 mg/kg of drug, respectively.³⁹ RA trials of infliximab therapy with or without concomitant MTX treatment revealed that immunogenicity was decreased by concomitant administration of MTX, due perhaps in part to the increase in the half-life of infliximab associated with MTX use. A multicenter trial of infliximab therapy in Crohn disease revealed that the induction of these anti-infliximab antibodies might have contributed to hypersensitivity reactions in some patients who had been treated with this drug. Although antibodies to adalimumab develop in about 12% of patients, the rate is reduced to 1% with concurrent MTX treatment. Routine testing for antibodies to these anti-TNF constructs is not currently recommended because the assays have not been standardized. However, as methods for testing for antibiologic antibodies have improved, the clinical consequences have become more apparent. Of 272 outpatients with RA treated with adalimumab and followed for over 3 years, 28% developed antiadalimumab antibodies, which were associated with lower adalimumab concentration and a decreased likelihood of minimal disease activity or clinical remission.¹²⁴

Autoimmune responses

Although nearly 40% of RA patients have serum antinuclear antibodies (ANA), the prevalence of ANA positivity increases with the use of anti-TNF agents. The mechanisms underlying autoantibody induction are uncertain but may relate to a compensatory increase in IL-10 or interferon- α , both of which are inhibited by TNF. Both can increase B-cell activity and are increased in patients treated with anti-TNF therapy. Antibodies to double-stranded DNA (ds-DNA) have also been reported to develop in about 5% to 10% of treated RA patients with all anti-TNF therapies. However, few (0.2% to 0.4%) develop symptoms consistent with drug-induced lupus.¹²⁵ Findings of ANA or dsDNA seropositivity are poorly predictive of subsequent toxicity, and thus pretreatment or routine monitoring of autoantibody levels is not recommended.

The rare occurrence of drug-induced lupus has been associated with all TNF inhibitors. Such patients need not meet criteria for lupus but must manifest a lupus-specific feature with evidence of ANA or dsDNA positivity and resolution with drug cessation. During drug development, there were few reports of TNF inhibitor-related rashes (discoid lupus, subacute cutaneous lupus, hypersensitivity vasculitis), serositis, cytopenias, and polyarthritides. Several points about drug-induced lupus related to the TNF inhibitors are worth summarizing:

- Common skin findings include malar rash, palpable purpura, or a “sunburnt” rash.
- The new onset of an acute large and small joint polyarthritis in a patient with previously stable RA treated with a TNF inhibitor may be an indication of drug-induced lupus.
- Fever, serositis, and cytopenias are common.
- ANA or dsDNA positivity is required to consider the diagnosis.
- Diagnostic confirmation rests with resolution of symptoms upon drug cessation.

Demyelinating syndromes

Multiple sclerosis (MS), optic neuritis, and other forms of demyelinating neurologic dysfunction have been described with TNF inhibitor use. This includes new-onset optic neuritis, *de-novo* MS, recurrence or flare of MS, encephalitis, myelitis, Guillain-Barré syndrome,¹²⁶ chronic inflammatory demyelinating polyneuropathy, neuropathy, transverse myelitis, seizures, and leukoencephalopathy. In most of these cases the disorder improved or resolved with discontinuation of TNF inhibitor therapy. It is unclear whether these rare events exceed those seen in the general or rheumatoid population,

and the epidemiology of demyelinating disorders in RA is also unknown. TNF antagonists may exacerbate existing demyelinating disease. A randomized study of the use of the p55 receptor lenercept in MS reported more flares in the patients receiving lenercept than in those receiving placebo.¹²⁷ Clinicians should exercise great caution when considering a TNF antagonist for a patient with preexisting or recent-onset optic neuritis, MS, or other demyelination disorder.

Congestive heart failure

TNF has been implicated in the pathogenesis of heart failure and cardiac cachexia. TNF levels are found to be consistently elevated in patients with congestive heart failure (CHF), and TNF has been shown to have negative inotropic effects on the myocardium and to cause myocyte dysfunction.

It was anticipated that TNF inhibition would improve cardiac outcomes in patients with CHF. However, clinical trials using high-dose infliximab (10 mg/kg) in patients with CHF were discontinued early because of an increase in death and worsening of CHF in patients with New York Heart Association (NYHA) class III or IV CHF.¹²⁸ Two large etanercept trials in patients with CHF were also terminated due to lack of efficacy and the observation that a high dose (25 mg three times weekly) was associated with worse cardiac outcomes. Despite the negative reported outcomes in CHF patients,¹²⁹ the use of TNF antagonists in RA patients was not associated with an increase in new-onset CHF in clinical trials. Caution is recommended when using anti-TNF agents in patients with CHF, especially those with NYHA class III and IV disease.

Cytopenias

Rare reports of pancytopenia and aplastic anemia have been described with anti-TNF therapy, and a minority of these cases resulted in death. Cytopenias developed in the first few weeks (median, 4 weeks) after initiation of TNF inhibitor therapy. Reasons for this sporadic association are unclear, but the occurrence of these cytopenias may be attributed to comorbidities or other myelosuppressive drugs in use. Periodic monitoring (every 3 to 6 months) of blood cell counts should be considered. Patients with features of blood dyscrasia (fever, pallor, bleeding, sore throat) should be evaluated for this complication.

Hepatotoxicity

Elevations in aminotransferase levels and hepatic failure have been reported with anti-TNF use (see Table 63.6). A 2003 FDA review of TNF safety revealed an unexpected 134 spontaneous reports of TNF inhibitor-related liver failure. When 50 cases were reviewed, confounding diagnoses or hepatotoxin exposure was found in 43 cases (e.g., sepsis, TB, isoniazid use, alcohol, viral hepatitis, graft-versus-host disease, use of hepatotoxic drugs). However, in seven cases (14%) no other cause could be identified, which suggests that TNF inhibitor use may have led to hepatic failure. In the clinical trials of infliximab and adalimumab, sporadic twofold to threefold elevations in liver function test values may have been attributable to the TNF inhibitor. There are also rare reports of hepatic failure with infliximab. Reactivation of chronic HBV infection has been reported following TNF inhibitor use. Hence patients at risk should be tested for HBV before drug initiation. One should be aware of these rare hepatic events, and hepatic enzyme levels should be monitored perhaps every 3 to 6 months.

Pregnancy and lactation

There are no controlled trials of TNF inhibitor therapy in pregnant women and there is a dearth of information on the use of TNF inhibitors in women who are or may become pregnant. Anti-TNF therapies are labeled by the FDA as a category B pregnancy risk. The BSRBR reported 88 live births from a total of 130 pregnancies in patients who received anti-TNF therapy before or during pregnancy. The rate of spontaneous abortion was highest among patients exposed to anti-TNF agents at the time of conception (with methotrexate or leflunomide, 33%; without methotrexate or leflunomide, 24%). This rate compared with 17% spontaneous abortions in those with prior exposure to anti-TNF agents and 10% spontaneous abortions in the control group. Ten terminations were performed.¹³⁰ The TREAT registry reported pregnancies in 66 patients with Crohn disease, 36 of whom were exposed to infliximab. No fetal malformations occurred, and no difference was seen between infliximab-treated and untreated patients in the rates of miscarriage ($P = .53$) and neonatal complications ($P = .78$).¹³¹

Placental transfer of maternal IgG antibodies to the fetus is an important mechanism that provides protection to the infant at a time when the fetal

humoral response is inefficient. IgG is the only antibody class that significantly crosses the human placenta mediated by FcRn expressed on syncytiotrophoblast cells. Thus it would be anticipated that biologics of the IgG class would cross the placenta. Unlike etanercept and the monoclonal antibody anti-TNFs, certolizumab lacks an Fc component. The U.S. drug label for certolizumab pegol states that, in an independent clinical study conducted in 10 pregnant women with Crohn disease treated with this drug, drug concentrations were measured in maternal blood as well as in cord and infant blood (n = 12) on the day of birth. The last dose of certolizumab pegol (400 mg for every mother) was given on average 19 days before delivery. Plasma certolizumab pegol concentrations were less than 0.41 to 1.66 µg/mL in cord blood, less than 0.41 to 1.58 µg/mL in infant blood, and 1.87 to 59.57 µg/mL in maternal blood. Plasma certolizumab pegol concentrations were lower (by at least 75%) in the infants than in the mothers, which suggests low placental transfer of certolizumab pegol. In one infant, the plasma certolizumab pegol concentration declined from 1.02 to 0.84 µg/mL over 4 weeks, which indicates that this biologic may be eliminated at a slower rate in infants than in adults.

The safety of anti-TNF therapy during lactation has not been established. Although it appears that the risk to the fetus and mother is negligible, further research is necessary. Many clinicians allow patients to conceive while receiving these therapies but stop the drugs at the time of conception. There are limited data on maintaining these drugs during pregnancy.

Cutaneous reactions

Rarely, cutaneous reactions have been ascribed to TNF inhibitors, including lupuslike rashes, hypersensitivity vasculitis, palpable purpura, urticaria, folliculitis, new-onset psoriasis, pernio, granuloma annulare, interstitial granulomatous dermatitis, lichenoid eruptions, bullous lesions, erythema multiforme, opportunistic skin infections, and cutaneous T-cell lymphoma (Box 63.5).

In a study of new-onset psoriasis reported as an adverse event among 9826 anti-TNF–treated and 2880 DMARD-treated patients with severe RA registered in the BSRBR, 25 incident cases of psoriasis were reported in patients receiving anti-TNF therapy and none in the comparison cohort. Furthermore, patients treated with adalimumab had a significantly higher rate of incident psoriasis compared with patients treated with etanercept or infliximab.¹³²

Unusual toxicities

One of the more unusual toxicities associated with TNF inhibitors is accidental injuries (e.g., falls, fractures) (Box 63.6). Improved well-being and resumption of physically aggressive activities appear to account for this unexpected occurrence. Also surprising are occasional reports of weight

gain with TNF inhibition. It is not clear if this is related to increased leptin levels or resolution of the anorectic effects of TNF.¹³³

Other unusual events reported with TNF inhibitor therapy include fibrosing alveolitis, adult respiratory distress syndrome, granulomatous lung disease, colonic perforations, vesicocolic fistula, paresthesia, neuropathy, seizures, foot drop, azoospermia, and glomerulonephritis (with and without lupus).¹³⁴⁻¹⁴²

Monitoring

Before initiating anti-TNF therapy, the clinician must weigh the potential clinical benefits of TNF-α inhibition against the potential adverse effects. Although specific laboratory monitoring is not mandated by current package labeling, physicians are strongly advised to order a complete blood count and liver function tests every 3 months (for the first 6 to 12 months) in patients treated with anti-TNF agents. Although autoimmune disorders (e.g., drug-induced lupus, multiple sclerosis) have arisen in anti-TNF–treated patients, there is no value in employing pretreatment or periodic serologic testing because these have no predictive value. In contrast, patients exhibiting signs of autoimmune disease should undergo serologic testing to help establish a diagnosis. Hepatitis B and C testing is also recommended before drug initiation. Patients should also be up to date with their immunizations before starting therapy, and inoculation with live vaccine should be avoided while the patient is receiving therapy.

At each visit the patient should be carefully evaluated for the risk or presence of infection, malignancy, demyelinating disorders, cytopenia, or any other comorbidities that may alter the patient's risk-benefit ratio. Physicians should suspend anti-TNF therapy and exercise caution when patients develop a serious infection.

CONCLUSION

Although currently available TNF blockers undoubtedly represent a considerable advance in the management of RA, future challenges remain. For example, further research is necessary to identify the ideal patient to receive

BOX 63.5 CUTANEOUS DISORDERS AND TUMOR NECROSIS FACTOR (TNF) INHIBITOR THERAPY

Anecdotal improvements with TNF	TNF inhibitor–induced cutaneous inhibitor therapy disorders
Pustular psoriasis	Lupus-like rashes
Acrodermatitis continua of Hallopeau	Hypersensitivity vasculitis, palpable
Psoriatic onychopachydermoperiostitis	Purpura
Pyoderma gangrenosum	Urticaria, angioedema
Pemphigus	Folliculitis
SAPHO syndrome	Interstitial granulomatous dermatitis
Graft-versus-host disease	Eosinophilic cellulitis
PAPA syndrome	Alopecia areata
Sarcoidosis	Pernio
Aphthous stomatitis	New-onset psoriasis

Necrobiosis lipidica diabetorum	Erythema multiforme
Hidradenitis suppurativa	
Scleroderma	Scleredema
	Subcutaneous fat atrophy
	Opportunistic skin infections
	Cutaneous T-cell lymphoma
	Oral epithelial dysplasia

BOX 63.6 ADVERSE EVENTS ASSOCIATED WITH USE OF TUMOR NECROSIS FACTOR INHIBITORS

- Common**
- Injection site reactions
 - Infusion reactions
 - Upper respiratory tract infections
- Uncommon**
- Serious infectious events
 - Mycobacterial infection
 - Fungal infection
 - Opportunistic infections
 - Viral infection (herpes zoster, hepatitis B)
 - Lymphoma and malignancy
 - Autoimmunity, autoantibodies, and lupuslike disease
 - Heart failure
 - Cytopenias
 - Demyelinating disorders
 - Hepatotoxicity
- Rare or uncertain relationship**
- Accidental injury
 - Weight gain
 - Pulmonary fibrosis
 - Asthma
 - Adult respiratory distress syndrome
 - Granulomatous lung disease
 - Colonic perforations
 - Vesicocolic fistula
 - Paresthesia
 - Neuropathy
 - Seizures
 - Foot drop
 - Asthenozoospermia
 - Glomerulonephritis
 - Proliferative lupus nephritis

TNF inhibition, the patient in whom TNF inhibition should be avoided, and the patient in whom the dosage of TNF inhibitor can be reduced. The identification of demographic, clinical, laboratory, and genetic factors that would predict clinical response or toxicity to these agents is highly desirable.

In all, anti-TNF therapy has given much hope and needed relief of disease activity with reduction in disability in our patients. The future application of these agents is an evolving story.

Kinase inhibition: a new therapeutic principle in rheumatology

■ RONALD FRITS VAN VOLLENHOVEN

- Tyrosine kinases are a large family of membrane-bound and intracellular enzymes with important regulatory functions in signaling cascades, including those involved in inflammatory responses. In recent years the blockade of tyrosine kinases has emerged as an important new therapeutic principle in many areas of medicine.
- Among tyrosine kinases, the four Janus kinases (JAKs) appear to be particularly suitable for therapeutic modulation in rheumatoid arthritis (RA) and other autoimmune inflammatory diseases.
- The JAK inhibitor tofacitinib was shown to be clinically effective at levels comparable to TNF-blockade. In 2012 it was approved by the U.S. Food and Drug Administration for the treatment of RA. Several other JAK inhibitors are currently in later-stage clinical development.

INTRODUCTION

If the advent of biologic treatments was the defining development in rheumatologic therapeutics over the past 20 years, it may well be that the second decade of the millennium will be the era of tyrosine kinase inhibitors. If so, this evolution will be in step with dramatic developments involving this very large class of molecules in other medical fields, most notably in oncology. More than a dozen such drugs have been approved in recent years for nonrheumatologic indications, in some instances opening up entirely new therapeutic possibilities. In rheumatology, the first tyrosine kinase inhibitor, tofacitinib, was approved in November 2012 by the U.S. Food and Drug Administration (FDA) for treatment of rheumatoid arthritis (RA), with more compounds under development.

TYROSINE KINASES

Tyrosine kinases are a group of around 90 enzymes capable of phosphorylating the amino acid tyrosine on another protein, which leads to conformational changes and typically activation of that protein. They are included in the much larger family of 518 kinases in the human “kinome”¹ (Fig. 64.1). Some tyrosine kinases are cell-surface receptors, whereas the nonreceptor tyrosine kinases serve as intracellular signal transducers, ensuring that binding of a transmembrane receptor for cytokines, growth factors, and so on, by its cognate ligand leads, by way of a sequence of activation events, to the initiation of transcription in the nucleus. For the future of therapeutics in rheumatology several tyrosine kinases are of paramount interest: the Janus kinases (JAKs), and the spleen tyrosine kinase (SYK).

Four tyrosine kinases comprise the JAK family: JAK1, JAK2, JAK3, and TYK2. The discovery of the critical role of the JAKs in human immunity represents a striking example of “bench-to-bedside” and then “bedside-to-bench” research, going from the identification of the JAKs as critical intracellular mediators in the intracellular process initiated by the binding of specific ligands to their cognate receptors on the cell surface^{2,3} to descriptions of genetic defects in the JAK3 enzyme in patients with severe combined immunodeficiency,⁴⁻⁷ which provided a link between the findings at the cellular and molecular level and the clinic. Subsequently, elegant work by multiple researchers clarified the precise role of the JAKs. A variety of mediator molecules, including some classical hormones such as prolactin,

growth factors such as erythropoietin, and around 60 immunologic mediators such as the interleukins and interferons, exert their effects by binding the type 1 and 2 cytokine receptors on the cell surface, containing the common γ chain; and the intracellular events following such binding, and leading to activation of specific transcription events, are critically dependent on the JAKs.⁸⁻¹² Thus, following binding of the receptor, a cascade of events is initiated to achieve the necessary activation (or suppression) of gene transcription in the nucleus. This cascade usually starts with the phosphorylation of the intracytoplasmic tail of the receptor molecules resulting in a conformational change, which in turn leads to the recruitment of various intracellular signaling molecules such as the signal transducer and activator of transcription (STAT) family of transcription factors. These are then phosphorylated as well, after which they dimerize and translocate to the nucleus where they initiate gene transcription. These events are summarized in Fig. 64.2. Table 64.1 lists some of the ligands dependent on the JAK activation pathway and adverse effects that can be expected when blocking these enzymes.

The spleen tyrosine kinase SYK is a nonreceptor tyrosine kinase with a key role in signaling following binding of several immunologically important receptors such as the B-cell receptor, the Fc γ receptor, and others. Thus SYK modulates intracellular signaling in cells bearing such receptors, including B cells, mast cells, macrophages, neutrophils, and synovocytes. SYK binds to the cytoplasmic region of these receptors through the immune receptor tyrosine-based activation motif (ITAM). Receptor binding results in ITAM phosphorylation activating SYK, which in turn activates various downstream tyrosine kinases including mitogen-activated protein kinases (MAPKs), phosphatidylinositol 3'-kinase and phospholipase C; this leads finally to increased production of various cytokines (including interleukin-6 [IL-6]) and inflammatory pathway effector molecules (including matrix metalloproteinases).

TYROSINE KINASE INHIBITORS

Tyrosine kinases can be readily inhibited *in vitro* by rather simple small molecules. However, it was not immediately obvious that inhibition of tyrosine kinases would be a useful therapeutic principle: the essential physiologic roles of the various tyrosine kinases, and the lack of specificity for most of the molecules, suggested that significant problems could emerge when trying to block these enzymes in the patient. Nonetheless, in a relatively short span of time it has become clear that favorable efficacy-toxicity ratios can be achieved with tyrosine kinase inhibitors in various diseases; this was shown first and foremost in oncology, but more recently in multiple clinical trials in rheumatology. The classes of therapeutics of greatest interest at the current time are the JAK inhibitors (sometimes referred to as *jakinibs*) and SYK inhibitors.

JAK inhibition

Tofacitinib

Tofacitinib (Xeljanz), formerly CP-690,550 (Fig. 64.3), is a small molecule with high affinity for and inhibitory activity against JAK3 (with a 50% inhibition concentration of 2.2 nmol/L) and almost as high activity against JAK1. It has somewhat lower activity against JAK2 (5.0 nmol/L), very low activity against TYK2, and virtually none against other kinases. JAK3 blockade interferes with the actions of, among other cytokines, IL-2, IL-4, IL-15, and IL-21; blockade of JAK1 inhibits signaling by interferon- α ,

Fig. 64.1 The large group of protein kinase enzymes in humans (the “kinome”) can be depicted based on their structural relationships. Most relevant for rheumatology therapeutics are the tyrosine kinases (TK) in the upper left part of the figure. (Based on Manning C, Whyte DB, Martinez R, Hunter T, Sudarsanam S. The protein kinase complement of the human genome. *Science* 2002;298:1912-34.)

interferon- β , interferon- γ , IL-6, and others; and blockade of JAK2 decreases signaling of IL-3, IL-5, and interferon- γ but also the hematopoietic growth factors erythropoietin, thrombopoietin, and granulocyte-macrophage colony-stimulating factor. Tofacitinib was effective in animal models of arthritis¹³ and was studied in a large phase 1/2/3 program for treatment of RA, while also being developed for use in transplantation and inflammatory bowel disease. The RA development program, summarized later, led to approval by the FDA, and tofacitinib is currently under review by the European Medicines Agency.

The phase 2 program for tofacitinib, which consisted of three randomized trials,¹⁴⁻¹⁶ established 5- to 10-mg twice-daily dosing. The half-life of 2 to 5 hours is probably insufficient to allow once-daily dosing, and dosages higher than 10 mg twice daily were associated with increased adverse effects. Thus the large phase 3 program that included multiple randomized trials investigated the 5- and 10-mg twice-daily dosing regimens. Results of two of these trials have been published to date, and several others have been reported at international meetings.

In the ORAL-STANDARD trial¹⁷ patients with RA were included who had moderate or high disease activity (defined as having at least six swollen and at least six tender joints, plus at least one elevated acute-phase reactant) despite receiving stable treatment with methotrexate (MTX). Low-dose glucocorticoids and nonsteroidal antiinflammatory drugs (NSAIDs) at stable doses were also allowed as concomitant medications, but no other disease-modifying antirheumatic drugs (DMARDs) or biologics were permitted. The patients were randomly assigned to receive placebo, tofacitinib

5 mg twice daily, tofacitinib 10 mg twice daily, or adalimumab 40 mg every other week. The primary outcome for the trial was achievement of 20% improvement according to the American College of Rheumatology scale (ACR20) after 6 months, which was reached by 28.3% of the placebo group, 47.2% of those receiving adalimumab, 51.5% of those given tofacitinib 5 mg twice daily, and 52.6% of those receiving 10 mg twice daily (Fig. 64.4). The active treatment groups fared statistically significantly better than the placebo group, and it was noted that the levels of improvement were numerically similar for all the active treatment groups. The same pattern was seen for a large number of secondary outcomes such as the ACR50 and ACR70 responses, European League Against Rheumatism responses, and so on. Thus the trial clearly established the clinical efficacy of tofacitinib, showing the clinical results to be numerically comparable to those of one of the most widely administered anti-tumor necrosis factor (anti-TNF) agents when used against a background of MTX. This trial did not assess the radiographic (structural) efficacy of tofacitinib.

The ORAL-SOLO trial¹⁸ investigated tofacitinib as monotherapy (allowing only NSAIDs and low-dose glucocorticoids as concomitant medications) compared with placebo. The standardized responses were significantly better with tofacitinib, with an ACR20 response rate at week 12 of 66%, 60%, and 27% for tofacitinib 10 mg, tofacitinib 5 mg, and placebo, respectively. In the ORAL-SYNC trial¹⁹ other DMARDs including MTX were allowed as background, and clinical efficacy over placebo was again demonstrated, so that at week 12 the ACR20 responses for tofacitinib 10 mg, tofacitinib 5 mg, and placebo were 58%, 53%, and 31%, respectively. In the

Fig. 64.2 Binding of a cytokine to its cognate receptor leads to phosphorylation of the intracellular domain of the receptor by specific Janus kinases (JAKs). Signal transducers and activators of transcription (STATs) are then recruited, bind to the receptor, and become phosphorylated by JAKs. This results in STAT dimerization, translocation, and regulation of gene transcription. Cytokines also activate PKB (AKT) and mTOR. Although not carefully studied, it is highly likely that blocking proximal cytokine signals will disrupt all downstream pathways. IFN, interferon; IL, interleukin. (From Kontzias A, Kotlyar A, Laurence A, Changelian P, O’Shea JJ. Jakinibs: a new class of kinase inhibitors in cancer and autoimmune disease. *Curr Opin Pharmacol* 2012;12:464-70.)

Fig. 64.3 Chemical structures of tofacitinib and fostamatinib, the tyrosine kinase inhibitors that are furthest along in clinical development for treatment of rheumatoid arthritis.

TABLE 64.1		
Main ligands dependent on the JAK activation pathway and adverse effects that can be expected when blocking these enzymes		
Ligands		Expected (“on-target”) adverse effects
JAK1	IL-2, IL-4, IL-6, IL-7, IL-9, IL-11, IL-10, IL-15, IFN-α, IFN-β, IFN-γ	Immune suppression, hyperlipidemia
JAK2	EPO, TPO, GM-CSF, IL-3, IL-5, IFN-γ	Anemia, neutropenia, thrombocytopenia
JAK3	IL-2, IL-4, IL-7, IL-9, IL-15	Immune suppression
TYK2	IFN-α, IFN-β, IFN-γ; IL-12	Immune suppression
SYK	Immunoglobulins	Immune suppression

EPO, erythropoietin; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; JAK, Janus kinase; SYK, spleen tyrosine kinase; TPO, thrombopoietin.

ORAL-STEP trial²⁰ tofacitinib was compared with placebo over 6 months in 399 patients who had experienced treatment failure with at least one anti-TNF agent, with MTX used as background therapy; ACR20 responses at week 12 for tofacitinib 10 mg, tofacitinib 5 mg, and placebo were 48%, 41%, and 24%, respectively. In the ORAL-SCAN²¹ trial, in which tofacitinib was tested against placebo on a background of MTX therapy in 797 patients who had shown an incomplete response to MTX, not only the clinical but also the radiographic outcomes were analyzed. The latter were investigated using the van der Heijde modification of the Sharp score (SvdH score), measured at baseline and after 1 year of treatment. In this trial, the clinical effects were again clearly superior for tofacitinib compared with placebo, but for the radiographic outcomes a statistically significant reduction of progression in the SvdH score was seen only at the higher dosage (10 mg twice daily) and not at the lower one. Progression in the placebo group in this trial was rather limited, which makes it mathematically more challenging to demonstrate an improvement, and numerically the results were not very different for the two tofacitinib dosages. However, the FDA did not accept the radiographic findings as evidence for inhibition of radiographic progression and did not give the radiographic claim to tofacitinib. Finally, the ORAL-START trial²² included 952 patients with RA who had not yet been treated with MTX—which often, but not always, means relatively early RA. Patients were randomly assigned to receive either MTX at dosages increased stepwise to 20 mg/wk, tofacitinib 5 mg twice daily, or tofacitinib 10 mg twice daily. ACR20, ACR50, and ACR70 responses were achieved by a larger proportion of patients receiving either dosage of tofacitinib, and radiographic progression was significantly decreased, compared with those given MTX (Table 64.2).

The combined evidence from these trials shows quite clearly that tofacitinib has clinical efficacy in RA whether given as monotherapy or in combination with MTX or other DMARDs, and that the clinical efficacy with background MTX is numerically similar to that seen with the anti-TNF agent adalimumab. Radiologic efficacy was statistically seen only for the 10-mg dose in patients with established RA, but a clear trend was observed for the lower dose, and both doses were effective in this regard in MTX-naïve patients. In addition, these trials also demonstrated that the clinical effect is seen soon after treatment initiation and that the efficacy is maintained with continued treatment over the 1- to 2-year time frame for follow-up in these trials. Improvements in functional status and quality-of-life measures were also noted in the studies.

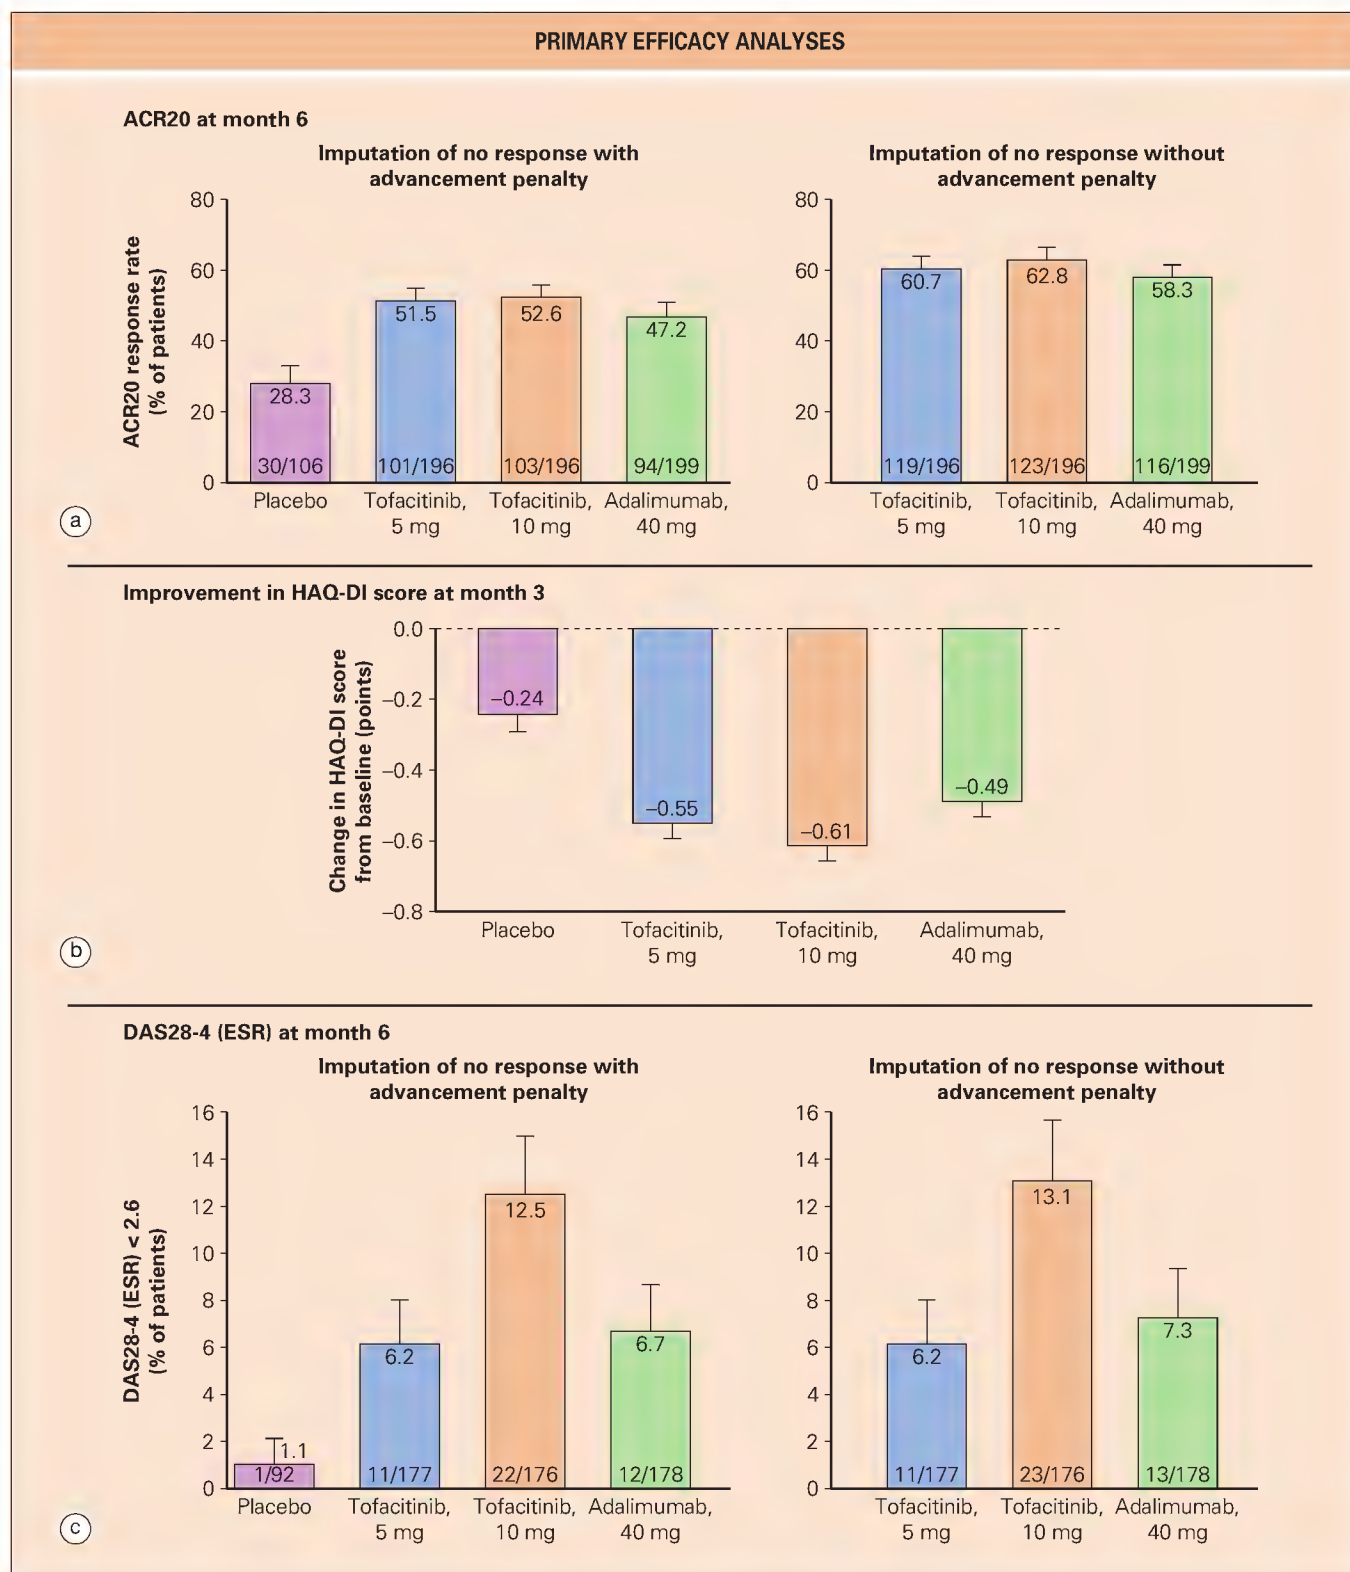

Fig. 64.4 Primary efficacy analyses of the ORAL-STANDARD trial of tofacitinib and adalimumab versus placebo in rheumatoid arthritis. (a) The numbers and percentages of patients with at least a 20% improvement as measured by the American College of Rheumatology scale (ACR20). The graph on the left shows the results of the analysis with imputation of no response with an “advancement penalty”; if the patient did not show a response to therapy by month 3, the treatment was considered to be a failure even if the patient had a response after month 6. $P < .001$ for the comparison of each active-treatment group with placebo. The graph on the right shows the results of the analysis with imputation of no response without the advancement penalty, these are the actual response rates at month 6 in the active-treatment groups irrespective of the response by month 3. The response without the advancement penalty cannot be calculated for the placebo group because patients in that group were blindly switched (“advanced”) to tofacitinib treatment if they showed no response by month 3. (b) Change in Health Assessment Questionnaire Disability Index (HAQ-DI) scores (which range from 0 to 3, with higher scores indicating greater disability) from baseline to month 3. A total of 98 patients in the placebo group, 188 in the 5-mg tofacitinib group, 185 in the 10-mg tofacitinib group, and 190 in the adalimumab group were included in this analysis. $P < .001$ for the comparison of each active-treatment group with placebo. (c) Numbers and percentages of patients with a Disease Activity Score for 28-joint counts based on the erythrocyte sedimentation rate (DAS28-4 [ESR]) of less than 2.6. Scores on the DAS28-4 (ESR) range from 0 to 9.4, with higher scores indicating more disease activity. As in (a), the graph on the left shows the results of the analysis with imputation of no response with the advancement penalty, and the graph on the right shows the results of the analysis with imputation of no response without the advancement penalty. For the graph on the left, $P < .05$ for the comparison of the 5-mg tofacitinib group and the adalimumab group with the placebo group, and $P < .001$ for the comparison of the 10-mg tofacitinib group with the placebo group. All data are expressed as means, with T bars indicating the standard error. (From van Vollenhoven RF, Fleischmann R, Cohen S, et al. Tofacitinib or adalimumab versus placebo in rheumatoid arthritis. *N Engl J Med* 2012;367:508-19.)

TABLE 64.2
Results of the ORAL-START trial of tofacitinib versus methotrexate (MTX) in MTX-naïve patients with rheumatoid arthritis

	MTX	Tofacitinib 5 mg bid	Tofacitinib 10 mg bid
No. of patients	186	371	395
ACR20 response rate (%)	50.5	71.0	75.8
ACR50 response rate (%)	27.2	46.6	56.2
ACR70 response rate (%)	12.0	25.5	37.7
DAS28 < 2.6 (%)	7.6	14.6	21.6
Mean change in modified total Sharp score (least-squares method)	0.84	0.18	0.04

For each analysis shown, the difference between the tofacitinib-treated groups and the MTX-treated group was statistically significant.
 ACR20/50/70, American College of Rheumatology 20%/50%/70% improvement criteria; bid, twice daily; DAS28, 28-joint Disease Activity Score.
 From Lee EB, Fleischmann RM, Hall S, et al. Radiographic, clinical and functional comparison of tofacitinib monotherapy versus methotrexate in methotrexate-naïve patients with rheumatoid arthritis. *Arthritis Rheum* 2012;64:S1049-5.

The safety and tolerability of tofacitinib were studied extensively in these trials as well as in longer-term extension studies²³ in which the medication was provided open label. The overall numbers of adverse events (where *adverse events* is the regulatory term indicating all medical events that occur during a trial, irrespective of attribution to the study drug; in other words, it is not the same thing as side effects) were generally slightly higher for tofacitinib than for placebo, with a suggestion that most of the increase was due to gastrointestinal symptoms and, to a lesser extent, to infections. The numbers of serious adverse events (defined as adverse events that lead to hospitalization, death, or various other serious long-term outcomes) were also somewhat higher for tofacitinib, as were the numbers of serious infectious events. The numerical increases in the latter were similar to those reported by clinical trials of many of the currently used biologics in RA, with rates of serious infectious events on the order of 4 to 6 per 100 patients per year. Because the background rate for patients with RA is not zero, this might be understood to mean that treatment with tofacitinib could lead to 1 to 4 serious infections per 100 patients treated for 1 year, an “attributable risk” quite similar to that seen with many of the currently used biologics in RA. During these trials, there were no major unexpected safety findings or “signals.” Cases of tuberculosis, other opportunistic infections, colonic perforations, and malignancies did occur, but to date the rates are similar to those seen with some or all of the biologics. However, there does appear to be an elevated rate of herpes zoster infection with tofacitinib.

Tofacitinib was also associated with various laboratory abnormalities. Elevations in liver enzyme levels were seen in around 5% to 10% of patients; most of the elevations were mild but some required dose adjustments or discontinuation. There were no cases of liver failure. Cytopenias including neutropenia, lymphopenia, anemia, and thrombocytopenia also occurred in 5% to 10% of patients, again with the majority being mild but with some more severe instances leading to discontinuation. These changes were reversible, and no major consequences were observed. In a limited number of patients severe anemia (hemoglobin level of less than 9 g/dL) was noted but resolved with drug discontinuation. Significant lymphopenia (fewer than 500 cells/mm³) was rarely seen. Tofacitinib should be temporarily withheld until there is recovery in the lymphocyte and/or absolute neutrophil count.

A very small but statistically significant increase in serum creatinine level was observed in the tofacitinib trials. The significance of this finding is unclear. Treatment with tofacitinib was associated with increases in low-density lipoprotein (LDL) and high-density lipoprotein (HDL) cholesterol levels and statin therapy may be required.

Overall, the laboratory abnormalities that are seen in the course of treatment with tofacitinib make it clear that such treatment will have to be monitored with laboratory testing. The cytopenias seen with tofacitinib can most likely be attributed to the weak JAK2-blocking effects of the molecule, whereas other laboratory abnormalities such as elevated lipid levels bear striking similarities to those seen with the anti-IL-6 agent tocilizumab. It is therefore reasonable to speculate that these adverse effects are a reflection of this particular action of the drug, and it might even be that many of the clinical benefits can be attributed to IL-6 blockade as well.

In November 2012 tofacitinib was approved for clinical use in the United States, but some questions remain at this time. While regulatory authorities

in other countries also approved this drug (Japan, Russia, Switzerland, as well as several countries in South America and the Middle East), the European Medical Agency did not grant approval, citing concerns on both efficacy and safety aspects.

The FDA approved the 5-mg twice-daily dosage as either monotherapy or in combination with MTX or other DMARDs in patients with active RA who had an inadequate response to or an intolerance of MTX. Measurement of complete blood count (CBC) and lymphocyte count as well as lipid levels is recommended at baseline and again at 4 to 8 weeks after initiation of therapy. CBC and lymphocyte count monitoring is recommended every 3 months thereafter. Routine monitoring of liver enzyme levels is also needed. Interruption of therapy is recommended if the absolute neutrophil count falls to between 500 and 1000 cells/mm³, and discontinuation is recommended if absolute neutrophil count or lymphocyte count is less than 500 cells/mm³. Interruption of therapy is also recommended for a hemoglobin decrease of more than 2 g/dL or a hemoglobin level of less than 8 g/dL.

It is evident that tofacitinib is an effective treatment with an adverse effect profile that is manageable in the context of rheumatology specialty care, so that the drug may reasonably be considered as an option for patients with active disease—and of course more so for patients who have not shown a response to other alternatives. The fact that tofacitinib is an oral agent may be attractive from the patient's point of view, and from a societal perspective it could be hoped that the simpler structure of the molecule compared with biologics would lead to a lower price. However, the current retail cost of the 5-mg twice-daily regimen is only marginally lower than that of the anti-TNF therapies.

Although tofacitinib is primarily being developed for use in RA (as well as transplantation, ulcerative colitis, Crohn disease, and psoriasis) additional rheumatologic indications for tofacitinib may emerge in the future, including spondyloarthritis, psoriatic arthritis, juvenile arthritides, and others. Additional studies will provide more information about questions such as whether dose escalation from 5 to 10 mg can induce a response in poor responders. Longer-term studies and greater patient exposure will provide important information about the drug's long-term safety profile, including risk of infections and malignancy. This information will be essential in determining the role and place of this agent.

Other JAK inhibitors

Several other JAK inhibitors are in clinical development for the treatment of rheumatic diseases (Table 64.3). The presence of divergent fine specificities for the different JAK enzymes could make important differences in the clinical benefits and risks, but only extensive clinical trials and, eventually, practical experience will allow a clear assessment of these compounds, which include the following:

- Decernotinib. Previously known as VX-509, decernotinib is a highly JAK3-selective inhibitor. In a phase 2 double-blind study, monotherapy with decernotinib at a range of dosages was tested against placebo in patients with RA who were biologic naïve and in whom DMARD treatment had failed. ACR20 responses for the highest dosages ranged from 61% to 66% compared with 29% for placebo. Some serious infections and liver enzyme elevations were noted, but there were no cytopenias and no effect on serum creatinine level.²⁴
- Baricitinib (LY3009104/INCB028050) blocks JAK1 and JAK2 and is a once-daily therapy. In a phase 2 trial involving 301 patients significant improvements were noted compared with placebo.^{25,26} At week 12 the ACR20 responses in the placebo group, the group given baricitinib 4 mg, and the group receiving baricitinib 8 mg were 41%, 75%, and 78%, respectively. As expected based on its JAK1, JAK2 profile some cases of anemia and elevated lipid levels were observed.
- Ruxolitinib is a JAK1/JAK2 blocker and the first such agent approved by the FDA for the treatment of myelofibrosis. Results of a phase 2 study of its use in RA were reported in abstract form²⁷ but never published. This compound is also being studied as a topical agent for treatment of psoriasis.
- GLPG0634 is a JAK1-selective agent. In a small proof-of-concept trial 24 patients were given GLPG0634 (half received 200 mg daily and half 200 mg twice daily), and 12 patients were given placebo. An ACR20 response was achieved by 83% of patients given GLPG0634 versus 33% of those given placebo. In this very small study, no anemia, increases in LDL level, elevated transaminase levels, or changes in creatinine level were seen.²⁸
- Several other JAK inhibitors are in development but with only animal data reported so far, including the JAK2 inhibitor CEP-33779^{29,30} and the combined JAK and SYK inhibitor R348.^{31,32}

TABLE 64.3

JAK inhibitors in clinical development

	Specific target(s)	Being developed for use in	Stage of clinical development
Tofacitinib	JAK3, JAK1 (JAK2)	RA, psoriasis, inflammatory bowel disease, transplantation	Phase 3
Decernotinib (VX-509)	JAK3	RA	Phase 2
Ruxolitinib	JAK2 (JAK1)	Myelofibrosis, polycythemia vera, essential thrombocythosis	Approved for myelofibrosis; phase 2/3 for other indications, unclear for RA
INCB18424 topical	JAK2 (JAK1)	Psoriasis	Phase 2
Baricitinib (INCB028050/LY3009104)	JAK1, JAK2	RA, psoriasis	Phase 2
CYT387	JAK2 (JAK1)	Myelofibrosis	Phase 2
GLPG0634	JAK1 (JAK2, TYK)	RA	Phase 2
AC-430	JAK2	RA, lymphoma	Preclinical

Additional JAK inhibitors for which preclinical data have been reported are R348, R723, BMS911543, AZD1480, and CEP33779. JAK, Janus kinase; RA, rheumatoid arthritis.

SYK inhibition: fostamatinib

Several inhibitors of the spleen tyrosine kinase (SYK) are also being developed for treatment of rheumatic diseases.

Fostamatinib (R788) is a prodrug; after oral administration it is rapidly converted to R406, an active inhibitor of SYK. It was effective in animal models of arthritis.³³ Three phase 2 trials of fostamatinib have been reported. In the first 12-week trial, and in a larger subsequent 24-week trial in patients who had never taken anti-TNF agents and had shown an incomplete response to MTX, good efficacy was seen, with a statistically significant higher level of improvement compared with placebo.^{34,35} In the 24-week trial ACR20 response rates at week 12 were 35%, 57%, and 67% in the groups receiving placebo, fostamatinib 150 mg once daily, and fostamatinib 100 mg twice daily, respectively. Clinical response was seen by week 1, and in most patients if a meaningful clinical response occurred it did so by week 8. However, a 3-month trial of fostamatinib in patients for whom prior anti-TNF therapy had failed did not demonstrate meaningful differences in the main clinical outcomes between the fostamatinib and placebo groups.³⁶ Subsequent analyses of the data for this nominally failed trial showed that patients with elevated C-reactive protein levels at baseline did benefit than patients who entered the trial with a normal C-reactive protein level but an elevated sedimentation rate, and an analysis of inflammation as documented by magnetic resonance imaging supported drug efficacy. It has been suggested that issues of trial design and baseline disease activity level contributed to the failure to show effects on the primary outcome. A recent press release announced that a fourth phase 2 trial had demonstrated the superiority of fostamatinib as monotherapy when compared with placebo but had failed to demonstrate equivalence with the anti-TNF agent adalimumab. An extensive safety follow-up of patients receiving fostamatinib therapy³⁷ demonstrated the occurrence of infections, neutropenia, and elevated liver enzyme levels, as well as a rather high frequency of diarrhea (27.6%) and hypertension (22.8%), but no anemia, increases in creatinine level, or increases in lipid levels. There were 14 malignancies reported in these trials. In June 2013 the phase 3 program for fostamatinib was terminated.

Other SYK inhibitors in the early stages of development include P505-15.

OTHER KINASE INHIBITORS

Although the JAK and SYK inhibitors have come the longest way in development as antirheumatic therapeutics, small-molecule inhibitors of other kinases are also being developed for various indications, and a use in autoimmune diseases may emerge.

Ibrutinib

Ibrutinib (PCI-32765) is a selective inhibitor of Bruton tyrosine kinase (Btk) and is being developed for treatment of several hematologic disorders. It was shown to have antiarthritic activity in an animal model.³⁸

p38 mitogen-activated protein kinases

A relatively large number of small-molecule compounds targeting the p38 mitogen-activated protein kinases (p38 MAPKs) have been evaluated over the past decade. p38 MAPKs are a group of protein kinases that are responsive to various stress stimuli. There are four p38 isotypes designated α , β , γ , and δ . Most compounds in clinical development targeted the α isoform. In preclinical studies in animal models many different p38 MAPK inhibitors showed evidence of a potential antiarthritic effect (reviewed by Bonilla-Hernán and colleagues³⁹). Some of these compounds were tested in early-phase trials and results were reported at international meetings but never published as full reports (reviewed in Bonilla-Hernán and colleagues³⁹ and in Genovese⁴⁰). A recurring finding in many of these trials was that an effect on C-reactive protein level was seen after only 1 to 2 weeks but abated after longer follow-up; clinical efficacy endpoints frequently were not met at longer time intervals, such as 12 weeks; and toxicities, including hepatotoxicity, were seen in many trials. Clinical results with the α -selective p38 MAPK inhibitor pamapimod were reported in more detail. In a phase 2 trial pamapimod was not significantly better than placebo,⁴¹ and in a double-blind, active agent-controlled phase 2 trial, pamapimod was less effective than MTX.⁴² Thus the initial optimism about these agents was followed by subsequent disappointment after many compounds failed in clinical testing.

Emerging therapeutic targets:
GM-CSF, IL-17, and IL-23

■ ALISON M. GIZINSKI ■ DAVID A. FOX

- Interleukin-17 (IL-17) is produced primarily by T cells. Granulocyte-macrophage colony-stimulating factor is produced primarily by activated T cells and macrophages. IL-23 is produced by antigen-presenting cells and tissue cells.
- Unique features of the biology and regulation of each cytokine point to specific strategies for either neutralization or downregulation by therapeutic biologics.
- In autoimmune diseases, cytokines function within a complex matrix of stimulatory and feedback loops such that perturbation of one cytokine is likely to influence the production and function of many others.

**POTENTIAL CYTOKINE TARGETS
IN RHEUMATIC DISEASES**

Multiple strategies can be used to inhibit the biologic effects of cytokines in rheumatic diseases, including monoclonal antibodies to cytokines or to their receptors, soluble receptors, and receptor antagonists. Additionally, cytokines can be inhibited by targeting their processing, intracellular signaling pathways, or synthesis (Table 65.1).

Design of inhibitors involves an understanding of their unique biologic activities, receptors, and signaling pathways while being mindful of potential complications that could result from their specific inhibition. Ideally, inhibitors of cytokines would be designed to alter the underlying immune dysfunction specific to a rheumatic disease while protecting the targeted tissues and allowing preservation of a host's immune defenses. As our understanding of the role of specific cytokines in rheumatic diseases evolves, more targets are being identified and potential new therapies are being tested for their safety and tolerability profiles.

**GRANULOCYTE-MACROPHAGE
COLONY-STIMULATING FACTOR****Description, receptor, function**

Granulocyte macrophage-colony stimulating factor (GM-CSF) is a cytokine produced primarily by activated T cells and macrophages. It mediates the activation of mature neutrophils, eosinophils, and macrophages to produce proinflammatory cytokines.¹ GM-CSF production is stimulated by lipopolysaccharide (LPS), tumor necrosis factor- α (TNF- α), interleukin-1 β (IL-1 β), and IL-23. GM-CSF is a 23-kDa glycoprotein with a four- α -helical structure that signals through a heterodimeric receptor composed of an α subunit and the common β chain (the common β chain/ β c/GM-CSFR β).^{2,3} The α subunit binds GM-CSF with low affinity. Once dimerization of the α subunit with the common α chain occurs, high-affinity binding is generated, thereby allowing signal transduction. The GM-CSF receptor (GM-CSFR) is expressed on neutrophils, dendritic cells, macrophages, eosinophils, and endothelial cells. The GM-CSFR complex activates the Ras-MAPK and JAK2-STAT (STAT1, STAT3, STAT5)-SOCS (SOCS1, SOCS3) pathways.^{4,5}

GM-CSF has colony-stimulating effects on bone marrow. However, GM-CSF-/- mice have normal numbers of hematopoietic cells, including neutrophils, monocytes, and eosinophils.⁶ In the absence of GM-CSF,

defective maturation of alveolar macrophages can result in pulmonary alveolar proteinosis.⁷ It is not known whether blockade of GM-CSF will lead to altered clearance of surfactant in healthy lungs.⁴

GM-CSF in rheumatic disease

Two distinct macrophage lineages have been described but not defined in rheumatic diseases. The M1 classically activated macrophages are involved in inflammation and host defense, and the M2 alternatively activated macrophages have antiinflammatory properties and are involved in tissue repair. GM-CSF may promote the development of M1 macrophages at sites of chronic inflammation. GM-CSF is present in the synovial fluid and serum of patients with rheumatoid arthritis. Additionally, some patients with Felty syndrome have been reported to experience flares of arthritis when receiving treatment with GM-CSF.^{8,9}

Synovial macrophages produce inflammatory mediators, including TNF- α , IL-1 β , and IL-6. The degree of synovial macrophage infiltration correlates with the radiologic progression of joint destruction and joint pain in patients with rheumatoid arthritis. Reduction of macrophage numbers on synovial biopsy specimens is used as a biomarker for the effectiveness of antirheumatic therapy.¹⁰ Elevated levels of GM-CSF and GM-CSFR have been measured in the synovial fluid and plasma of patients with rheumatoid arthritis.¹¹⁻¹⁴ Taken together, these data suggest a role of GM-CSF in rheumatoid arthritis.

Clinical trials

Mavrilimumab is a fully humanized IgG1 monoclonal antibody that binds to the α subunit of GM-CSFR, thereby preventing interaction of GM-CSF with its receptor. In a phase 1 dose escalation study of 32 patients with rheumatoid arthritis, adverse events were reported with similar frequency in all treatment cohorts. One patient experienced face and neck urticaria during infusion of the 10-mg/kg dose that resulted in discontinuation of the infusion. The study was not designed to evaluate clinical efficacy, but no significant change in Disease Activity Score (DAS)28 was seen in any of the cohorts. In mavrilimumab-treated patients with moderate disease activity (DAS28 lower than 3.2) at baseline, mean DAS28 scores were significantly reduced at 28 weeks.¹⁵ A phase 2 study of mavrilimumab in patients with rheumatoid arthritis has been completed.¹⁶ In this 12-week, sequential ascending-dose study, 233 patients received either mavrilimumab (10, 30, 50, or 100 mg every other week) or placebo on a background of methotrexate therapy. The primary endpoint was the proportion of mavrilimumab-treated subjects achieving a decrease in DAS28-C-reactive protein (CRP) of 1.2 or greater from baseline versus placebo at week 12. By week 12, 55.7% of mavrilimumab-treated subjects met the primary endpoint (DAS28-CRP reduction of 1.2 or greater) versus 34.7% in the placebo group ($P = .003$). The 100-mg group showed significant improvement in comparison to placebo in the primary endpoint (DAS28-CRP); the American College of Rheumatologists (ACR) 20 response was 69% in the 100-mg group versus 40% in the placebo group ($P = .005$). Clinical response was observed by week 2. The short-term safety profile did not demonstrate any significant issues.

Namilumab, a humanized monoclonal antibody to GM-CSF, is undergoing a phase 1b dose escalation study in patients with rheumatoid arthritis.¹⁷ KB003 is a recombinant human anti-GM-CSF IgG1K monoclonal antibody. KB003 has undergone a phase 2b trial in patients with rheumatoid arthritis who failed previous treatment with a biologic agent. The results of the study have not been reported to date.¹⁸ MOR103 is a fully humanized monoclonal antibody to GM-CSF. A phase 1b/2a study involving an intravenous

TABLE 65.1
Cytokines, their sources, receptors, signaling pathways, and major functions

Cytokine	Cellular source	Receptor	Signaling pathway	Function
GM-CSF	Macrophages and activated T cells	GM-CSF α /GM-CSFR β	Ras-MAPK and JAK2-STAT1, STAT3, STAT5-SOCS1, SOCS3	Colony-stimulating factor on bone marrow; activation of mature neutrophils, eosinophils, and macrophages
IL-17A, IL-17F	T cells, $\gamma\delta$ T cells, NK T cells, neutrophils, eosinophils	IL-17RA/IL-17RC	TRAF6, MAPK, TAK1, NF- κ B	IL-6, IL-8, and GM-CSF production by epithelial cells and fibroblasts, production of IL-1 β and TNF- α from monocytes, MMP synthesis
IL-23	Macrophages, DCs, T cells, B cells, endothelial cells	IL-12RP1/IL-23R	JAK2, Tyk2, STAT3, STAT4	Maintains Th17 cells, induces memory T cells to proliferate and produce IFN- γ and IL-17

DCs, dendritic cells; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN- γ , interferon- γ ; JAK, Janus kinase; MAPK, mitogen-activated protein kinase; MMP, matrix metalloproteinase; NF- κ B, nuclear factor-kappa B; NK, natural killer; Ras, rat sarcoma; SOCS, suppressor of cytokine signaling; STAT, signal transducer and activator of transcription; TAK, transforming growth factor- β -activated kinase; Th17, type 17 helper T cell; TRAF, TNF receptor-associated factor; Tyk, tyrosine kinase.

preparation has been completed in patients with rheumatoid arthritis. The results have not been published, but development of a subcutaneous preparation is under way.¹⁹

INTERLEUKIN-17

Description, receptor, function

The IL-17 family has six identified members designated A to F, of which IL-17A and IL-17F are the most studied. IL-17A and IL-17F are homodimeric cytokines, but human CD4+ T cells can also produce an IL-17A/F heterodimer that has inflammatory effects.²⁰ IL-17A and IL-17F are produced by activated CD4+ and CD8+ T cells. IL-17A is produced mainly by type 17 helper T cells (Th17 cells). Th17 cells are derived from CD4+ T cells that have been stimulated with IL-1 β and transforming growth factor- β (TGF- β), with roles for IL-6, IL-21, or IL-23.²¹ IL-23R is expressed by Th17 cells, and IL-23 is a survival factor for Th17 cells and induces the production of IL-17A from the Th17 cells. IL-17B and IL-17D are expressed in resting CD4+ T cells and can induce the secretion of IL-6, IL-8, and GM-CSF in fibroblasts, epithelial cells, and endothelial cells.^{22,23}

The IL-17 family members bind to a distinct class of cytokine receptors. IL-17RA is a subunit of a multimeric preformed receptor complex with IL-17RC. This complex undergoes a conformational change when bound.²⁴ IL-17R is expressed on monocytes, macrophages, chondrocytes, osteoblasts, and fibroblasts.²⁵

IL-17 is a proinflammatory cytokine that induces epithelial cells to produce IL-8, which is a chemoattractant for neutrophils, and IL-17 also induces the production of IL-1 β and TNF- α from monocytic cells.²⁶ Production of antimicrobial peptides is induced by IL-17 in epithelial cells, thus suggesting a role for IL-17 in host defense.²⁷

Interleukin-17 in rheumatic disease

High levels of IL-17A have been found in the sera, synovial fluid, and synovial biopsy specimens of patients with rheumatoid arthritis.²⁵ Additionally, increased levels of IL-17 expression in the synovium were predictive of more severe joint damage in a prospective study of patients with rheumatoid arthritis.²⁸ IL-17 contributes to cartilage and bone destruction through multiple mechanisms. It inhibits chondrocyte metabolism, causes proteoglycan breakdown, and induces the production of metalloproteinases associated with cartilage destruction.²⁵ IL-17 can trigger osteoclastogenesis by upregulating receptor activator of nuclear factor- κ B ligand (RANKL) on osteoblasts, which allows interaction with RANK on the osteoclasts responsible for bone erosion.²⁵ IL-17A can act synergistically with TNF- α and IL-1 β to induce inflammatory mediators in synoviocytes, osteoblasts, myoblasts, and chondrocytes.²⁴ IL-17RA and IL-17RC are overexpressed in rheumatoid arthritis.²⁴ Taken together, these findings make IL-17 and its receptor promising targets in the treatment of rheumatoid arthritis.

Clinical trials

IL-17A blockade with secukinumab, a human IgG1 κ monoclonal antibody to IL-17A, has completed phase 1/2 trials on rheumatoid arthritis. In the phase 1 trial on rheumatoid arthritis, the endpoint for efficacy, an ACR20 response, was met.²⁹ In a phase 2 study on rheumatoid arthritis, the primary efficacy endpoint, an ACR20 response at 16 weeks, was not reached. Upper respiratory infections and pharyngitis occurred more frequently in the

secukinumab-treated groups.³⁰ Efficacy, safety, and tolerability studies in patients with rheumatoid arthritis, ankylosing spondylitis, and psoriatic arthritis are currently in progress.³¹⁻³³

Ixekizumab is a monoclonal antibody to IL-17A. A phase 1 placebo-controlled, proof-of-concept study was completed in patients with rheumatoid arthritis, with DAS28 at week 10 being the primary efficacy endpoint. Changes in DAS28 met significance only when the responses of all treated groups were combined and compared with the placebo group (−1.7) at week 10. The incidence of leukopenia and neutropenia was increased in ixekizumab-treated patients, but without any report of increased infection in active drug- versus placebo-treated patients.³⁴

In a randomized, phase 2 double-blind study, 260 patients naïve to biologic agents received subcutaneous placebo or ixekizumab (3, 10, 30, 80, or 180 mg), and 188 TNF-IR patients received placebo or ixekizumab (80 or 180 mg) at weeks 0, 1, 2, 4, 6, 8, and 10 with concomitant disease-modifying antirheumatic drug therapy. A significant dose-response relationship was seen in biologic-naïve patients at week 12. Significant differences versus placebo were seen for DAS28-CRP reductions in biologic-naïve patients and in TNF-IR patients at all ixekizumab doses, with a rapid onset of efficacy occurring within 1 week after the first dose. A reduction in DAS score of −1.8 was observed in the 180-mg biologic-naïve group versus −0.6 in the placebo group. The frequency of adverse events was similar across treatment arms.³⁵

INTERLEUKIN-23

Description, receptor, function

IL-23 is a member of the IL-12 cytokine family and is composed of two subunits, the p40 and p19 peptides. IL-23 is produced by macrophages and dendritic cells and binds to a heterodimeric receptor composed of IL-12R β 1 (shared with IL-12R) and IL-23R (Fig. 65.1).^{36,37} T cells, natural killer cells, monocytes/macrophages, and dendritic cells express IL-23R receptor.³⁸ IL-23 induces memory T cells to proliferate and produce interferon- γ , mediates the development and proliferation of IL-17-producing CD4+ Th17 cells, and stimulates antigen presentation by dendritic cells.³⁸ In a mouse model of demyelinating disease, IL-23 induced central nervous system and peritoneal macrophages to produce IL-1 β and TNF- α .³⁹ By inducing macrophages to produce IL-1 β and TNF- α , IL-23 may perpetuate a local proinflammatory environment. IL-23 signals through the JAK-STAT pathway. Binding of IL-23 to its receptor leads to activation of JAK2 and Tyk2, which phosphorylate and activate STAT3 and STAT4.^{36,40,41} The association of a STAT4 polymorphism marked by rs7574865 has been described in patients with rheumatoid arthritis, systemic lupus erythematosus, Crohn disease, and ulcerative colitis.⁴² Additionally, a polymorphism in the IL23R gene has been linked to susceptibility to Crohn disease.⁴³

Interleukin-23 in rheumatic diseases

IL-23 has been identified in the sera and synovial fluid of patients with rheumatoid arthritis, and expression of the p19 subunit is increased in the synovial fibroblasts of patients with rheumatoid arthritis.⁴⁴ IL-23 serum levels correlate with markers of rheumatoid arthritis disease activity, and IL-23 synovial fluid levels correlate with the presence of erosions in patients with rheumatoid arthritis.^{44,45} Cultured synoviocytes from rheumatoid arthritis patients produced IL-23 and IL-23R, and IL-23 blockade led to decreased production of TNF- α , IL-1 β , and IL-6.⁴⁶

IL-23 IS A MEMBER OF THE IL-12 CYTOKINE SUPERFAMILY

Fig. 65.1 Interleukin-23 (IL-23), a member of the IL-12 cytokine superfamily, is composed of two subunits, p40 and p19. IL-23 binds to a heterodimeric receptor composed of IL-12Rβ (shared with IL-12R) and IL-23R. Ustekinumab is a monoclonal antibody that binds to the shared p40 subunit of IL-12 and IL-23. JAK2, Janus kinase 2; Tyk, tyrosine kinase 2; STAT4, signal transducer and activator of transcription 4.

Monocytes and dendritic cells in psoriatic skin plaques express high levels of the p19 and p40 subunits of IL-23.⁴⁷ Elevated serum levels of the p40 subunit of IL-23 were found to distinguish between patients with psoriatic arthritis and healthy individuals.⁴⁸

Patients with ankylosing spondylitis were found to have a higher proportion of IL-23R-expressing T cells in their peripheral blood because of a marked increase in IL-23R+ γδ T cells.⁴⁹ IL-23 serum levels were higher in patients with spondyloarthritis than in healthy individuals.^{50,51} Monocytes isolated from the peripheral blood of patients with ankylosing spondylitis that were differentiated into macrophages produced more IL-23 in response to LPS than did controls.⁵²

Infections with *Salmonella* and *Mycobacterium* have been described in individuals with homozygous mutations of either the *IL12B* gene, which encodes the p40 subunit common to IL-12 and IL-23, or the *IL12RB1* gene, which encodes a subunit of IL-12R and IL-23R.⁵³ This suggests that IL-23 may play an important role in defense against pathogens, with implications for safety issues in blockade of IL-23. Two recent meta-analyses performed to look for an association between blockade of IL-12/IL-23 for chronic plaque psoriasis and cardiovascular events had conflicting results; of note, both studies excluded trial data from patients with psoriatic arthritis.^{54,55} Further studies are needed to address this possible risk.

Clinical trials

An oral IL-12/IL-23 inhibitor, apilimod mesylate, was tested in patients with rheumatoid arthritis to determine safety, pharmacokinetics, and synovial tissue outcome but failed to induce a significant clinical response.⁵⁶

A phase 2 trial of ustekinumab, a human monoclonal antibody that binds to the shared p40 subunit of IL-12 and IL-23 and blocks their signaling, was performed in patients with psoriatic arthritis. The primary endpoint was an

TABLE 65.2

Cytokines, potential inhibitors, and rheumatic disease targets

Cytokine	Method of inhibition	Disease targets
GM-CSF	Monoclonal antibody to GM-CSF Monoclonal antibody to GM-CSFRα	Rheumatoid arthritis
IL-17A, IL-17F	Monoclonal antibody to IL-17 Monoclonal antibody to IL-17R IL-17R fusion protein	Rheumatoid arthritis, psoriatic arthritis, spondyloarthritis
IL-23	Monoclonal antibody to the p40 subunit of IL-12 and IL-23 Monoclonal antibody to the p19 subunit of IL-23	Rheumatoid arthritis, psoriatic arthritis, spondyloarthritis

GM-CSF, granulocyte-macrophage colony-stimulating factor; IL-17, interleukin-17.

ACR20 response at week 12, which was achieved by 42.1% of subjects in the treatment group and 14.3% of subjects in the placebo group ($P < .001$). Adverse event rates were reported to be similar in both groups.⁵⁷ Ustekinumab-treated patients experienced improved physical function and health-related quality of life.⁵⁸

A phase 3 trial of ustekinumab in patients with psoriatic arthritis has been completed.⁵⁹ Six hundred fifteen patients with active psoriatic arthritis were randomized to receive ustekinumab, 45 or 90 mg, or placebo at weeks 0 and 4 and every 12 weeks thereafter. Stable concomitant methotrexate was allowed. Previous anti-TNF therapy was an exclusion. The primary endpoint was the ACR20 response at week 24. A significantly greater proportion of patients treated with ustekinumab, 90 mg (49%), than placebo-treated patients (23%) achieved an ACR20 response at week 24. Nearly half the patients used concomitant methotrexate at baseline, but this did not alter the likelihood of benefit of ustekinumab versus placebo.

A second phase 3 study of ustekinumab is recruiting participants with and without previous exposure to anti-TNF agents. The primary outcome measure is the proportion of patients with an ACR20 response at 24 weeks.^{59,60}

A proof-of-concept study is recruiting subjects to investigate the safety and efficacy of ustekinumab in patients with active ankylosing spondylitis who have had an inadequate response to nonsteroidal antiinflammatory drugs.⁶¹

A phase 2 trial of ustekinumab and CNTO 195, an antibody to the p19 subunit of IL-23, is recruiting participants to evaluate the efficacy of these agents in patients with rheumatoid arthritis and concomitant methotrexate therapy. The primary outcome is the ACR20 response at week 28.⁶²

CONCLUSION

GM-CSF, IL-17, and IL-23 each have important proinflammatory roles in rheumatoid arthritis and other rheumatic diseases. Further understanding of these cytokines and their regulation has advanced rapidly. Notwithstanding potential safety concerns, careful therapeutic trials of blocking strategies directed against each of these molecules are justified by the available animal data, *in vitro* studies, and measurements performed in patients with rheumatic diseases (Table 65.2).

Biosimilars in rheumatology

■ JEFFREY SIEGEL

- Recent legislation and guidelines provide an abbreviated path to approval of biosimilars.
- Because of the large size and complexity of biologics, the path to approval of biosimilars will be more complicated than that for generic small-molecule drugs.
- In rheumatology, demonstration of biosimilarity for approval will probably include clinical trials in most cases.
- Immunogenicity can have serious consequences for safety and efficacy and will be a key issue for approval of biosimilars.

Small-molecule drugs such as statins and nonsteroidal antiinflammatory drugs have a well-established pathway for the development and marketing of generic versions following a period of exclusivity for the innovator product. In contrast, until recently no similar pathway was available for the development of biosimilar versions of biologic drugs because of the complexity of their chemical makeup and manufacture. Recent developments have provided a legal and regulatory pathway for the approval and marketing of biosimilars, thereby increasing the likelihood that biosimilar versions of selected commonly prescribed biologics may become available in the not too distant future. These newer developments include the passage of legislation permitting the approval of biosimilars and the issuance of draft guidance by the U.S. Food and Drug Administration (FDA) on the process for demonstrating that a proposed biosimilar version of an approved biologic is, in fact, biosimilar to the innovator molecule. The criteria that will be applied for demonstrating biosimilarity are critical for assuring health care providers and patients that the biosimilar medications that patients receive have comparable safety and efficacy as the innovator product. The process of demonstrating biosimilarity is made more difficult by the large size and complexity of many biologics and by the propensity of many biologics to be immunogenic.

GENERIC DRUGS VERSUS BIOSIMILARS

When a new drug is approved, the manufacturer (sponsor) goes through a process of characterizing the product chemically and characterizing its toxicology in preclinical models, its pharmacokinetics, and its safety and efficacy in humans. After approval of a new drug by the FDA, a system of legal protections provides the pharmaceutical company sponsor a period of marketing exclusivity based on patent rights and on provisions that delay the marketing of generic versions until the period of marketing exclusivity is completed. The system is intended to reward innovation by companies that discover and develop new therapies in areas of unmet medical need. The Waxman-Hatch Act of 1984 (Drug Price Competition and Patent Term Restoration Act) allowed generic versions of small-molecule drugs to be approved in a simplified process when the marketing exclusivity and patent protection expire. The Waxman-Hatch Act defines a process for approving generics based on their bioequivalence to the innovator drug following submission of an Abbreviated New Drug Application (ANDA). In general, a sponsor submitting an ANDA provides evidence that the generic version has the same chemical structure as the innovator molecule and is bioequivalent in pharmacokinetic (PK) studies in humans. In this abbreviated pathway, if a generic drug is determined to be bioequivalent, the sponsor is not required to perform toxicology studies in animals or to conduct safety or efficacy studies in humans. This process allows generic drug manufacturers to market generic versions of drugs at lower cost to consumers.

Since ANDAs are not required to include studies of safety and efficacy in humans, the FDA relies on evidence of safety and efficacy for the approval of generic drugs that was not derived by the ANDA sponsor. For applications that rely solely on chemistry and bioequivalence, the FDA uses a provision termed 505(j) to allow the use of evidence not derived by the sponsor. In other situations in which a sponsor submits a New Drug Application (NDA) for a version of a previously approved drug, for which additional information beyond chemistry and bioequivalence are required, a similar provision, termed 505(b)(2), allows the FDA to rely on evidence not derived by the sponsor.

The term *biologic* refers to a number of different types of products, including therapeutic proteins, vaccines, blood products, and cell and gene therapies. In their practice rheumatologists prescribe several different types of biologics, such as vaccines, blood products (e.g., intravenous immune globulin), and therapeutic proteins, including monoclonal antibodies and soluble receptors (Fc fusion proteins). This chapter focuses on therapeutic proteins, although similar considerations may apply to other types of biologics. In contrast to small-molecule drugs, which are manufactured synthetically, biologics are made in biologic systems and the active moiety is then extracted and purified. Biologics are generally larger and much more complex molecules than small-molecule drugs. In addition, the properties of a biologic are sensitive to subtle changes in manufacturing that may not be apparent based on chemical characterization. Because of these important differences between small-molecule drugs and biologics, the Waxman-Hatch Act, which allowed approval of generic drugs, did not contain the necessary provisions to apply to biologics. Therefore, until recently there was no abbreviated pathway to approval of biosimilars.

WHY IS A DIFFERENT PROCESS NEEDED FOR BIOSIMILARS?

The abbreviated process for approval of generic small-molecule drugs relies on the idea that knowing that the chemical structure of a generic version and its distribution in the human body (bioequivalence) are the same as for the innovator product provides sufficient evidence to predict that its efficacy and safety will also be equivalent. The process of demonstrating chemical identity is made easier by the fact that small molecules are, by definition, small and have a relatively simple chemical structure. They are manufactured via chemical processes that are designed and carefully controlled to ensure that all molecules of the drug are identical. Strict controls are placed on the manufacturing process to make sure that other materials used in the chemical reactions are removed and any impurities are kept within specified, narrow limits. Of note, the manufacturing process for producing a generic is not usually the same as that for producing the innovator product, but chemical characterization and demonstration of bioequivalence ensure that the resulting molecules are sufficiently similar despite differences in their manufacture.

In contrast to small-molecule drugs, the composition and structure of therapeutic proteins and other biologics are much more complex (Table 66.1). To begin with, therapeutic proteins are much larger (typically 150 kDa for monoclonal antibodies versus less than 1 kDa for small-molecule drugs). In addition, knowing the primary structure alone (i.e., the amino acid sequence) does not allow prediction of the overall structure of the protein (Fig. 66.1). Rather, the amino acid residues in the nascent polypeptide chain interact with neighboring residues to form secondary structures (e.g., α -helices and β -sheets), and the protein folds to form its final structure in space (tertiary structure). Finally, many therapeutic proteins, including monoclonal antibodies, consist of multiple polypeptide chains interacting with one another in a specific manner to form its characteristic quaternary

Fig. 66.1 Protein complexity: structure.

TABLE 66.1
Key differences between small-molecule drugs and biologics

Small-molecule drugs	Biologics
Generally small, less complex molecules	Large, highly complex molecules
Uniform	Complex mixture of related forms
Synthesized chemically	Produced in biologic systems
Generics process	Biosimilar process
Demonstration of similar structure, bioequivalence in pharmacokinetic studies	Demonstration of similarity in structure, function, preclinical studies, pharmacokinetics, pharmacodynamics, and clinical safety and efficacy
Immunogenicity—typically not an issue	Immunogenicity highly dependent on small changes in structure and on manufacturing
Interchangeable with the reference product	Requires independent demonstration of interchangeability

structure. The precise primary, secondary, tertiary, and quaternary structure of therapeutic proteins determines their biologic properties.

Biologics are not synthesized by using chemical methods; they are produced in living organisms. Monoclonal antibodies and other therapeutic proteins are typically grown in cell lines. The process begins with the introduction into cell lines of DNA coding for the polypeptide chains making up the therapeutic protein. The cell line transcribes the DNA and translates it into protein. The cell line is expanded in large incubators. The cells are then harvested and the therapeutic protein is extracted and purified. By allowing the cell line to produce the therapeutic protein, the same biologic control mechanisms that cells ordinarily use to ensure the proper sequence and folding of native proteins generate the proper sequence and folding of biologics in the engineered cell line.

The cell line also modifies the protein in a variety of ways, termed *post-translational modifications*, by using the same enzymes and processes that it uses in generating native proteins (Fig. 66.2). These modifications include the addition of sugars, such as mannose and sialyl residues, and modification of amino acid residues by oxidation or deamidation. These modifications are not absolutely uniform; that is, individual protein molecules may

Fig. 66.2 Examples of modifications inherent or attributable to the manufacturing process. (Adapted from Steven Koslowski, Food and Drug Administration.)

differ from one another in their particular modifications, such as the extent of glycosylation. Further modifications may be contributed by the manufacturing process. As a consequence of these changes in the proteins, biologics are not generally composed of a uniform set of identical molecules as small-molecule drugs are. Instead, biologics are composed of an array of closely related molecules sharing a common amino acid sequence and similar structure but possessing a range of posttranslational modifications.

The considerations just mentioned illustrate why the pathway defined for approval of generic versions of small-molecule drugs would not work for biologics. Because of the complexity of biologics and the different manufacturing processes that the innovator and the biosimilar manufacturer would use, it is likely that a biosimilar would differ from the reference biologic in ways that could affect its biologic activity in unpredictable ways. Hence the safety and efficacy of a biosimilar cannot be assumed based on chemical characterization and PK bioequivalence alone. In the past a sponsor who wished to develop a biosimilar version of an innovator molecule after exclusivity had expired could have characterized the molecule in the same manner as for a new molecular entity (i.e., conducting studies

of toxicology in nonclinical models and safety and efficacy studies in humans). However, no abbreviated pathway for the development of biosimilars was available until recently with the approval of new legislation and guidance from the FDA.

LEGISLATIVE AND REGULATORY FRAMEWORK FOR BIOSIMILARS

After many years of consideration the U.S. Congress passed new legislation that provided for approval of biosimilars. The Biologics Price Competition and Innovation Act of 2009 (BPCI Act) provided an abbreviated pathway for the approval of biosimilar versions of an FDA-licensed reference biologic that permits sponsors of biosimilars to use evidence that they had not derived themselves when the biosimilar version had been shown to be biosimilar to the reference biologic. However, even though the BPCI Act provided a pathway for approval of products shown to be biosimilar to or interchangeable with a reference approved biologic, it did not specify how biosimilarity or interchangeability would be determined. That awaited further communication from the FDA on how the BPCI Act would be implemented.

In February 2012, the FDA issued a draft guidance document titled “Guidance for Industry: Scientific Considerations in Demonstrating Biosimilarity to a Reference Product,” which provides general principles regarding the evidentiary standard that the FDA will apply in reviewing applications for approval of biosimilars.¹ The draft guidance states that because of the complexity of the proteins, biosimilar products are unlikely to be identical to the reference product. Furthermore, minor differences in structure may have a significant impact on safety and efficacy. Hence, an approach such as that used for evaluating generic small-molecule drugs, which relies on demonstrating structural identity and bioequivalence based on PK studies, would not be sufficient for evaluating biologics. Rather, the draft guidance states that a 351(k) application for a biosimilar should contain evidence of biosimilarity based on analytic studies, animal studies, and one or more clinical studies of a condition of use for which the reference biologic is approved.

In its development program, a biosimilar sponsor would provide data to demonstrate that the biosimilar is very similar to the reference product. If the FDA reviewed the data and agreed that the product was biosimilar, it would conclude that the product met the standards for approval via the 351(k) pathway. What would happen if the differences were too large for the product to be deemed biosimilar? Would any other path to approval be available? In principle, the answer is yes. If a reference biologic is no longer under patent protection, a biosimilar manufacturer could follow the same pathway to approval as for a new molecular entity (NME) by conducting analytic studies and demonstrating safety and efficacy in animal and human studies. However, such a molecule could not take advantage of the abbreviated pathway of a 351(k) application. Approving such a product as an NME would be similar to the approach taken for biologics such as novel monoclonal antibodies that have the same target as an approved biologic but are derived independently and therefore have a distinct molecular composition. Similarly, the BPCI Act does not define an abbreviated path for products that are like a reference biologic but are designed to be improved in some manner, such as more potent or less immunogenic than a reference product. Such products are sometimes termed “biobetters” and would presumably need to follow the standard process for approval as an NME since the differences would preclude demonstrating similarity. Although it may seem counterintuitive that a more potent molecule would not meet the standards of biosimilarity, it must be kept in mind that a more potent product could have a different safety profile. In summary, a 351(k) application provides an abbreviated pathway for products that are versions of a reference product and in which any differences are so small they can be judged to be biosimilar.

MOLECULAR COMPLEXITY OF BIOLOGICS

In general, as detailed earlier, biologics are much more complex than small-molecule drugs. Their structure is determined not only by their amino acid sequence (primary structure) but also by their secondary structure (α -helix and β -sheet formation), tertiary structure (overall folding of the polypeptide chain), and the interaction between polypeptide chains making up the protein (quaternary structure). In addition, proteins undergo glycosylation and a variety of posttranslational modifications that have important implications for their structure and chemical and biologic properties. Structural analysis of protein biologics demonstrates that even after rigorous

Fig. 66.3 Protein microheterogeneity.

purification a biologic is made up of a mix of molecules that vary within a range (Fig. 66.3). Based on the known variation it has been estimated that a given antibody molecule could theoretically have as many as 10^8 potential variants (see Fig. 66.2). Manufacturers of biologics carefully characterize the chemical and structural properties of their products and set specifications for the allowable amount of variation to ensure that a new batch is within the range of characteristics seen with previous batches. Only batches that fall within specifications are allowed to be marketed and prescribed.

During the life cycle of a biologic the manufacturer will occasionally make changes in the manufacturing process, for example, to make the process more efficient or to reduce impurities. How do they make sure that the resulting product has the same properties as product from the previous manufacturing process? They do this by assessing comparability of the new and previous products. First, any process changes undertaken cannot fundamentally change the product. Otherwise, it would be considered a new product and would need to undergo testing as an NME. However, even seemingly small changes in manufacturing can lead to some change in the structural properties of the resulting product.² In general, if the two products are sufficiently similar, only biochemical characterization may be sufficient. If changes are present but they appear to be minor, bioequivalence studies may be required. Finally, if the changes are more than minor, clinical studies demonstrating similarity may be needed as well.

The process that manufacturers undertake when they make a manufacturing change in a biologic is highly regulated. The process is defined, in part, in documents such as the International Congress on Harmonisation (ICH) Q5E guidance document.³ This document acknowledges that because of the complexity of protein biologics, comparability does not necessarily mean identity. Rather, it means “. . . that they are highly similar and that the existing knowledge is sufficiently predictive to ensure that any differences in quality attributes have no adverse impact upon safety or efficacy of the drug product.” In particular, demonstrating comparability means having a detailed understanding of how the structural attributes of a protein relate to its function.

The variations observed in a protein molecule have important implications for the safety and efficacy of biologics. In some cases these variations determine the biologic activity of the resulting product. For example, experiments with human erythropoietin (HuEPO) have demonstrated that differences in its sialic acid-containing carbohydrate content have a direct relationship with its PK properties and bioactivity. Darbepoetin alfa is a recombinant human erythropoietin (rHuEPO) engineered to have two extra carbohydrate chains. Egrie and colleagues^{3a} showed that darbepoetin alfa had a longer half-life and was more potent than rHuEPO. Another example relates to monoclonal antibodies with antitumor activity, which are typically IgG1 antibodies possessing core fucosylation. Antibody-dependent cellular cytotoxicity (ADCC) mediated by natural killer (NK) and other cells is an important mechanism of tumor killing. Recent studies have shown that defucosylation of these antibodies leads to great receptor binding on NK cells and enhanced ADCC.⁴ Thus, glycosylation controls a property critical to the efficacy of these products.

Even though it is complicated for a manufacturer to demonstrate comparability after a change in manufacturing, it is much more complicated still for a biosimilar manufacturer to demonstrate biosimilarity to a reference biologic. When a biologic manufacturer makes a manufacturing change, everything is generally kept the same except for the change in the process

Fig. 66.4 Potential differences with a different manufacturer.

being undertaken. In contrast, when a biosimilar manufacturer undertakes to produce a biosimilar, many changes in the process with respect to the reference product will take place (Fig. 66.4). First, the sequence of the gene for the protein may or may not be the same as the reference product. In addition, to introduce the gene into cells it will probably have a different DNA vector. Then the host cell line used for expression will probably be different, with the potential for changes in protein processing within the cell. The cell lines will then be grown in a different process, and purification of the protein will probably differ. How much each of these differences will contribute to differences in the final product cannot be predicted.

In summary, the molecular complexity of biologics and the complex nature of the manufacturing process mandate a process for determining the similarity of biosimilars to reference biologics that is different from the process used for generic small-molecule drugs. Subtle differences in the molecular composition of biologics can have profound effects on their biologic activity. The FDA strictly regulates changes in the manufacturing process for approved biologics to ensure comparability.

CASE HISTORY: ERYTHROPOIETIN AND PURE RED CELL APLASIA

One important property of biologics that can interfere with their efficacy and safety is immunogenicity, namely, the ability to induce an immune response to the protein that results in antitherapeutic antibodies (ATAs). Many variables influence the immunogenicity of biologics, including the extent of foreign (i.e., nonhuman) sequences, route of administration, dose, concomitant medications, and disease status. The FDA requires careful assessment of immunogenicity for new biologics. The consequences of immunogenicity vary depending on the type of antibodies produced, their concentration and affinity, and the nature of the biologic in question. For monoclonal antibodies, ATAs can result in loss of efficacy either by binding to the active site of the biologic and thereby neutralizing its activity or by increasing its clearance in the body so that the concentration of the biologic falls below the therapeutic range. ATAs to monoclonal antibodies can also result in adverse events by inducing hypersensitivity reactions, vasculitis, or infusion or injection site reactions. Adverse events related to the immunogenicity of monoclonal antibodies generally dissipate when the biologic is cleared from the body.

For biologics that are also normal constituents of the human body, in addition to the aforementioned consequences of immunogenicity, there is the additional possibility of the ATA cross-reacting with the native protein and consequently reducing its concentration or neutralizing its activity with the potential for effects on normal physiology. When ATAs are produced to a biologic that is also a form of a naturally occurring protein and the ATAs cross-react with that native protein, the ATA may persist long after the biologic is cleared. If that native protein has a nonredundant function, the consequences can be serious. The occurrence of anti-EPO antibody-mediated pure red cell aplasia (PRCA) with certain products of rHuEPO illustrate the occurrence of ATAs and the potential consequences.

Several versions of rHuEPO have been approved for certain forms of anemia, including the anemia related to chronic kidney disease and the

Fig. 66.5 Pure red cell aplasia (PRCA) with recombinant human erythropoietin. A small change in formulation led to unpredicted immunogenicity. HSA, human serum albumin; s.c., subcutaneous.

anemia related to the effects of concomitant myelosuppressive therapy. Initially, when rHuEPO was introduced into medical practice, the adverse event PRCA was observed rarely. Specifically, for the 10 years from 1988 to 1998, PRCA occurred in only three patients. This rare condition is caused by antibodies to rHuEPO that cross-react with and neutralize native EPO. Since the human body does not have alternative mechanisms for inducing erythropoiesis, these antibodies inhibit erythropoiesis and lead to selective loss of red cells. Beginning in 1998 an outbreak of PRCA was seen that was associated with the use of rHuEPO (Fig. 66.5).⁵ In the 2 years between 1998 and 2000, 13 cases of PRCA were reported in France—12 in patients receiving the product Eprex with the active ingredient epoetin alfa and 1 in a patient receiving NeoRecormon containing epoetin beta, both products that are marketed exclusively outside the United States. By 2004 a total of 175 cases had been reported for Eprex, 11 for NeoRecormon, and 5 for Epogen, another rHuEPO product.

What led to this dramatic increase in the occurrence of PRCA with rHuEPO? Several potential changes were identified that may have precipitated the change in immunogenicity. First, beginning in the 1990s there was a switch from administration by the intravenous route to subcutaneous administration. This may have contributed since the subcutaneous route of administration of proteins can be more immunogenic.⁶ However, alone it would not fully explain the observation that most cases occurred in Europe. In 1998 the formulation of Eprex was changed to substitute human serum albumin (HSA) because of concern on the part of European health authorities that HSA could transmit a variant of Creutzfeldt-Jakob disease. The reformulated, HSA-free version of Eprex contained polysorbate 80 as a stabilizer and had different recommendations for handling the product. In contrast, other rHuEPO products prescribed in the United States, Epogen

(epoetin alfa) and Aranesp (darbepoetin alfa), had always included HSA as a stabilizer. A variety of explanations have been offered on how changes in the formulation of Eprex marketed outside the United States could have led to an increase in immunogenicity. In general, the explanations center on the likelihood that the new formulation, because of either micelle formation, leachates from rubber stoppers, or a combination of both, was less stable and led to aggregate formation, which increased the likelihood of antibody formation. After recognition of the risk for PRCA, measures were taken to ensure proper storage, handling, and administration of Eprex, and the rubber plungers in the prefilled syringes were replaced by Teflon-coated plungers. After the institution of these new measures, the incidence of PRCA decreased by more than 80% worldwide.

The story of PRCA associated with a change in the formulation of an rHuEPO product illustrates several important principles. First, changes in the manufacture of a biologic may affect its biologic properties in important ways that cannot always be anticipated. Even the sophisticated structural studies used to characterize a biologic may not always detect changes that can affect important properties such as immunogenicity. The experience with PRCA and rHuEPO is relevant to the optimal approach to characterizing biosimilars since by its nature the production of biosimilars involves a change in manufacturing with respect to the reference product. In Thailand it was noted that the occurrence of PRCA was concomitant with the increased use of different follower rHuEPO products.⁷ To confirm the association between these products and PRCA, 30 patients who had experienced loss of efficacy with such rHuEPO products were studied. Of the 30, 23 had anti-EPO antibodies and PRCA. In response to this epidemic, the FDA of Thailand instituted a registry to estimate the immunogenicity and efficacy of rHuEPO products. Such follower products with inadequate approval as generics were not marketed in the United States. Another example of the important impact that subtle changes in manufacturing and administration of biologics can have on immunogenicity relates to HX575, a biosimilar rHuEPO approved for intravenous administration in Europe. When HX575 (Binocrit) was studied in a randomized trial by subcutaneous administration against Eprex, both products were able to raise hemoglobin levels to a similar degree with similar dosing. Nonetheless, the trial had to be stopped early because ATAs developed in two patients in response to subcutaneous HX575, one of whom also had PRCA.^{8,9}

WHAT WILL THE FOOD AND DRUG ADMINISTRATION REQUIRE TO APPROVE A BIOSIMILAR?

In the draft guidance the FDA described an approach to evaluate a proposed biosimilar product. This approach assumes that biosimilars are unlikely to be identical to the reference product. They proposed a stepwise approach that begins with analytic studies of the proposed biosimilar, followed by animal studies and then clinical studies in humans. Each step is intended to assess the extent of differences from the reference product. If analytic studies and animal studies indicate few differences, the likelihood of demonstrating biosimilarity on study in humans increases. In particular, if few differences are seen, the subsequent clinical studies may be more targeted. The FDA justified this stepwise approach by noting that “even minor structural differences” in a biologic can affect its safety, purity and potency. In particular, they noted that minor process impurities can increase the likelihood of an immune response to a biologic and that current analytic methods may not be sufficient to detect relevant differences.

The first step that the FDA recommended for assessment of biosimilarity is study of the structure and function of the molecule followed by animal toxicology studies to identify potential toxicities in humans and to make sure that no additional toxicities are seen beyond what was observed with the reference product. If these studies indicate similarity of the proposed biosimilar to the reference biologic, studies could commence in humans to assess pharmacokinetics, pharmacodynamics, and finally safety and efficacy for at least one of the approved indications. Of particular concern is immunogenicity since ATAs can influence both the safety and efficacy of a biologic and changes in manufacturing are known to have the potential to influence immunogenicity. Assessment of immunogenicity begins with study of the development of ATAs in animals. In general, immunogenicity of biologics in animals does not predict immunogenicity in humans. However, when assessing proposed biosimilars, comparison of the antibody response in animals to that of the reference biologic can identify differences that may predict the development of ATAs in humans. The next step in assessing immunogenicity is comparing ATAs in humans for the proposed product and the reference biologic in clinical trials conducted before approval (pre-market). The extent of premarket immunogenicity testing depends on a

variety of factors, including the potential consequences of ATAs, such as the possibility of anaphylaxis or situations in which the biologic is a form of a naturally occurring, nonredundant protein in the body (e.g., rHuEPO). Finally, additional postmarket testing for ATAs may be required.

In the end the agency states that it will consider the totality of the evidence in determining biosimilarity and making approval decisions. The FDA has discretion to not require one or more required elements. However, which elements that the FDA may not require in any given situation is unknown. Sponsors should meet with the FDA to discuss their program during development so that the FDA can offer advice on the sponsors' proposed development plan.

WHAT WILL A CLINICAL DEVELOPMENT PROGRAM FOR A BIOSIMILAR LOOK LIKE?

The final step in development is studies in humans. Since the objective of these studies is to demonstrate biosimilarity, they will by nature be comparative studies to the reference biologic. The clinical development program will begin with PK and pharmacodynamic (PD) studies. PK studies will serve to demonstrate that similar blood levels are observed with the proposed biosimilar and the reference product but will also assess whether there may be differences in the way that the human body handles the proposed biosimilar that could reflect subtle but potentially important differences in structure or formulation. PD measures assess drug effects on the body and are generally chosen to reflect the mechanism of action (e.g., the effect of tumor necrosis factor [TNF] inhibitors on C-reactive protein [CRP]). PD studies serve to determine whether there are any differences in the way that the proposed biosimilar affects the body in mechanistically important ways.

When PK and PD studies have been completed, the final step is one or more clinical trials for a relevant indication. The design of such a trial follows from the objectives of the trial, namely, to demonstrate similarity to the reference biologic. To illustrate some of the considerations in designing a clinical development program, let us consider a proposed biosimilar to a TNF inhibitor for rheumatoid arthritis (RA). The study arms would be the proposed biosimilar and the reference product at one or more of the approved doses. When the reference TNF blocker is approved both as monotherapy and in combination with methotrexate (MTX), the biosimilar sponsor would need to decide whether to study monotherapy, to enroll patients with background MTX, or to study both conditions of use. On the one hand, TNF blockers are frequently added to MTX in patients with an inadequate response to MTX.¹⁰ Immunogenicity can be higher with monotherapy than in combination with MTX for some products, and the guidance document recommends that when a sponsor wishes to extrapolate the immunogenicity findings from one indication to another, the condition of application that is most sensitive to detect a difference in immunogenicity should be used. In situations in which monotherapy with the reference product is more immunogenic, a study in monotherapy could be considered a more sensitive test for differences in immunogenicity.

Since the goal of a biosimilar development program is to show similarity, the FDA recommends the use of an equivalence design, which is closely related to the noninferiority design that is commonly used to compare a new product with an active control but with some important differences (Fig. 66.6). In a noninferiority study the new product is compared with the active control with the objective of showing that it is at least as good as the active control. Since it is statistically impossible to show that two products are exactly as good as each other, a noninferiority study instead aims to show that the new product is no more than a very small amount inferior. Because noninferiority designs generally do not include a concurrent placebo control, it is necessary to make an assumption about how well a placebo control would have done if one had been included. To design such a trial then calls for evidence from previous placebo-controlled trials about the effect size of the active comparator. For example, if the American College of Rheumatology (ACR) 20 response for the active comparator was 55% in previous trials and the placebo response was 20%, the effect size was 55% – 20% = 35%. Then the trial needs to set a noninferiority margin (i.e., the size of inferiority that must not be exceeded). In general, the noninferiority margin is based on what is a clinically acceptable margin of noninferiority by taking into account the fact that very small noninferiority margins require commensurately large sample sizes. If the study sets a noninferiority margin of 10%, a successful trial shows an effect size of 25% or more, thereby demonstrating preservation of at least 71% of the effect size of the reference product (25%/35%). A comparative trial of this type would also allow a comparison of the safety of the two products side by side.

An additional complexity of a biosimilar clinical development program is that the clinical trial should demonstrate that the proposed product is

Fig. 66.6 Potential clinical trial to compare a proposed biosimilar with an approved tumor necrosis factor (TNF) blocker. ACR20, American College of Rheumatology 20% response; CI, confidence interval; EP, endpoint; MTX IR, methotrexate incomplete responder; RA, rheumatoid arthritis.

neither worse nor better than the reference product. Therefore, the optimal clinical trial design is actually an equivalence study rather than a noninferiority study. An equivalence trial would be designed to demonstrate that the proposed product is neither inferior nor superior to the reference product by the specified margin (e.g., 10%). Although this requirement may seem counterintuitive, the concern is that if a proposed biosimilar is actually more effective than a reference product, it may be more potent, in which case the safety of the product cannot be assumed to be the same.

A well-designed and well-conducted equivalence trial would provide clinical evidence that the proposed product behaves clinically like the reference product with respect to safety and efficacy, thus supporting the evidence of similarity provided by previous studies to support a conclusion of biosimilarity.

AREAS OF UNCERTAINTY

The FDA draft guidance document on biosimilars contains information on two additional important areas related to biosimilars: interchangeability and whether a biosimilar will receive all indications for which the reference biologic is approved or just a subset of the indications. These are both complex areas in which it is uncertain how the considerations described in the draft guidance will be applied in practice.

Interchangeability

Under most states' pharmacy substitution laws, pharmacists can substitute a generic for a reference product without requesting permission from the prescribing health care provider unless the prescriber specifically declines substitution. The scientific rationale for interchangeability for a generic small-molecule drug is that the approval process for the generic includes a review of evidence for structural identity and bioequivalence within the human body that ensures that the two products will behave every bit the same.

The FDA has a provision to allow interchangeability. Labels for biosimilars will contain a statement on whether the product has or has not been shown to be interchangeable with the reference product. However, the assumptions behind allowing an abbreviated pathway for approval of generic small-molecule drugs and biosimilars are distinctly different. Unlike proposed generic small-molecule drugs, proposed biosimilars are assumed to be likely not to be identical to the reference product. The process for assessment of biosimilars is a step-by-step procedure designed to show that the two products are very similar and that any small differences will not affect safety and efficacy. Whether the data that support biosimilarity are adequate to allow interchangeability is a different matter.

A key issue in concluding that the biosimilar can be interchanged with the reference product is whether the immunogenicity will be the same. If it is not, there is a risk that ATAs could develop in a patient who is switched to a biosimilar and prevent a clinical response to the reference biologic when

it is switched back. In addition to biosimilarity, to conclude interchangeability a biosimilar sponsor will need to provide evidence that after repeated administration the safety and efficacy of switching are no different from staying with the reference product. Although it makes intuitive sense that evidence of this type would support interchangeability, it is not at all clear at present how a sponsor would design a program to provide the necessary data. Among the questions a sponsor would need to answer are how safety and efficacy would be evaluated and how it would be demonstrated that immunogenicity after switching back is no different from that in patients who stayed with the reference product.

What indications will biosimilars be approved for?

When generic small-molecule drugs are approved, their label is derived from the label of the innovator product. With some exceptions the generic label lists the indications for which the innovator product is approved. One exception to this rule is that if the innovator conducted clinical trials to receive an additional indication, that additional indication may be protected for a time by exclusivity provisions. The BPCI Act allows approval of a biosimilar for additional indications beyond those studied in the clinical trials for approval by extrapolating from the indications that were studied and relying on evidence of safety and efficacy from the reference product. However, the decision to grant additional indications is not automatic. Rather, the sponsor will need to provide scientific justification for why similar safety and efficacy as the reference biologic would be expected for any additional indications. The rationale for this more cautious approach for biosimilars is that small differences are expected between reference biologics and proposed biosimilars and it is important to provide assurance that those small differences will not affect safety and efficacy for an indication (e.g., ankylosing spondylitis) for which a sponsor wishes to extrapolate safety and efficacy from another indication (e.g., RA).

For the biologics currently used in rheumatology, many are approved for multiple indications. The biosimilar draft guidance document specifies some of the considerations that the FDA will take into account in deciding which indications that a biosimilar will receive. Such considerations include any possible differences in mechanism of action, in PK characteristics, and in safety between the various indications. With respect to the mechanism of action, relevant considerations include the target or receptor for the relevant activity of the product, the location and expression of the receptor or target, binding of the product to the target, and what is known about the relationship between the structure of the product and its binding to the relevant target. For PK considerations the biosimilar sponsor will need to take into account how the PK properties of a reference biologic product differ between different indications, how the toxicities differ between different indications, and any other factors that may influence the safety and efficacy of a product differently in different indications.

Many examples of how biologics are used differently in different indications can be cited. Adalimumab is approved for RA, for Crohn disease, and for ulcerative colitis. However, the approved dose for RA is 40 mg subcutaneously every other week, whereas for Crohn disease a 160-mg loading dose on day 1 and then 80 mg on day 15 followed by 40 every other week beginning on day 29 is recommended. This difference in dosing presumably reflects a difference in the relevant targets in Crohn disease versus RA and the differential ability of a given concentration of adalimumab achieved in blood to block the target. For some biologics the rate of immunogenicity is lower when they are administered in combination with immunosuppressives than when administered as monotherapy. For these biologics the condition of use (concomitant immunosuppressives versus monotherapy) influences the rate of immunogenicity. In situations such as these, when the relevant properties of a biologic differ between indications, the draft guidance document recommends using the more sensitive condition for extrapolating from one condition of use to another. Thus, if immunogenicity is more frequent in one condition of use, study of that condition could allow extrapolation to the condition with less immunogenicity, but not vice versa. Similarly, if a particular toxicity is more frequent in one condition of use, it may not be possible to extrapolate safety from study of the indication in which that toxicity is less frequently observed.

One particular condition of use that is not addressed specifically in the draft guidance is use in children. For small-molecule drugs and biologics that are approved for adults, the Pediatric Research Equity Act (PREA) requires that the sponsor study the product in children with the same condition. On this basis several TNF blockers have been studied and approved for use in children with polyarticular juvenile idiopathic arthritis. It remains an open question whether the FDA would grant an indication for children without some study in pediatric patients. PK and PD studies in children could be carried out, but efficacy studies would be quite challenging since

comparative noninferiority or equivalence trials could require large sample sizes, which may be impractical. Whether pediatric studies would be required for biosimilars as they are for innovator biologics is an unanswered question.

Because biosimilars are not expected to be identical to the reference biologic and because small differences in structure can affect safety and efficacy in unpredictable ways, an approved biosimilar would not automatically receive all the indications as the reference product. Instead, the sponsor will need to provide scientific rationale to support approval for additional indications beyond the ones that they study directly. The extent of study required to obtain approval for other indications will depend on how close the proposed biosimilar is to the reference product and the likelihood that small variations could cause differences in safety and efficacy for the different indications.

APPROACH TO BIOSIMILARS IN OTHER REGIONS

The World Health Organization (WHO) and the European Union have also issued guidelines for the evaluation of biosimilars. The WHO guidelines, issued in 2009, provide a framework similar to that incorporated into the FDA guidance document.¹¹ The pathway defined by the European Union (Fig. 66.7) is similar but not identical to that in the United States and predates the U.S. legislation. Legislation allowing biosimilars was first passed in the European Union in 2004, and overarching guidelines describing the principles to be used when assessing biosimilars were released in 2005.¹² Guidelines have also been proposed for quality (i.e., product attributes) and for nonclinical and clinical considerations. Product-specific guidelines have been issued for insulin, somatotropin, granulocyte colony-stimulating factor, rHuEPO, and others. Somatotropin was the first biosimilar approved via this pathway in 2006. Currently, approximately a dozen biosimilars have been approved. The majority of them fall into the categories of somatotropin, rHuEPO alfa, and filgrastim. These molecules are smaller than monoclonal antibodies and are considerably less complex. At the time of this writing no monoclonal antibody or Fc fusion protein biosimilar has been approved in the European Union.

The process for demonstrating that a proposed biosimilar will have similar safety and efficacy as a reference product is generally similar in the European Union to the process described earlier in the United States, with some important differences. Both regions recognize that because of the complexity of biologics, the approach used for approval of generic small-molecule drugs is not scientifically appropriate. In both regions it is recognized that the differing manufacturing processes used by the innovator and biosimilar sponsor will lead to some differences between the two products. The E.U. guidelines recognize that although currently available assays are very good in discerning differences between protein molecules, it is not possible to predict how minor structural differences will translate into physicochemical or clinical differences.

In the European Union, approval of a biosimilar requires demonstration of the similar nature of the proposed biosimilar and the reference product. The biosimilar sponsor conducts comparability studies to demonstrate that the two products are sufficiently similar with respect to quality, safety, and efficacy. This is analogous to the FDA-defined process that calls for demonstrating that the two products are sufficiently similar to be deemed biosimilar, thereby ensuring that there are “no clinically meaningful differences . . . in terms of the safety, purity or potency of the product.” As in the United States, the assessment begins with studies of structure and function *in vitro*. At this point the degree of similarity that was demonstrated guides the need for subsequent studies. The E.U. guidelines allow the possibility that dose-comparative and highly sensitive PD studies could convincingly show comparability in a clinically relevant manner, thereby obviating the need for clinical trials. However, to use a PD study, the PD marker must be an accepted surrogate (i.e., evidence that an effect on the surrogate reliably predicts a corresponding effect on the clinical outcome measure). Since PD measures that are accepted surrogates are not available for most rheumatologic diseases, PD studies are unlikely to be the basis for approval of biosimilars for these indications. Therefore, normally it is expected that similar clinical efficacy between the proposed biosimilar and the reference product would be demonstrated in “adequately powered, randomised, parallel group comparative clinical trial(s), preferably double-blinded and normally equivalence trials,” which is very close to the standard enunciated by the FDA. Other aspects of the E.U. approach that are similar to the FDA approach include the recommendation to use the most sensitive model for PD and clinical studies and allowance of extrapolation to other indications with adequate justification.

The E.U. guidelines also specifically relate to assessment of the postmarketing safety of biosimilars. Pharmacovigilance may need to be greater than what is ordinarily called for, including the possibility of participating in new or existing registries. Sponsors must address how postmarketing safety will be assessed with respect to indications that used extrapolation but were not specifically studied with the proposed biosimilar, rare serious adverse events seen with the reference biologic, and new safety signals as with any marketed biologic. The brand name of the product given to a patient should be recorded to aid in traceability. Traceability could be important in situations in which one or more biosimilars are on the market along with the innovator product.

Guidelines of the European Medicines Agency (EMA) do not specifically offer recommendations concerning interchangeability. Rather, interchangeability (or substitution) is left to the member countries.

In the past, developing countries have allowed marketing of products that are purported to be biosimilars but have not undergone the rigorous evaluation described in the U.S., E.U., and WHO guidelines. It is not clear in all instances that these products are, in fact, biosimilar to the reference product. Key to the U.S. and EMA approval process for biosimilars is conduct of head-to-head studies comparing the proposed biosimilar with the reference product. In other countries with less rigorous regulatory processes, such studies may not be required for marketing. Studies evaluating alternative rEPO products outside the United States and European Union

Fig. 66.7 Framework for E.U. assessment of biosimilar products. Epo, erythropoietin; G-CSF, granulocyte-colony stimulating factor; IFN, interferon; LMWH, low-molecular-weight heparin. (From McCamish M, Woollett G. *Worldwide experience with biosimilar development*. *MABs* 2011;3:209-217.)

by analytic techniques demonstrated that they were not comparable to the originator product.¹³ In contrast, analytic studies comparing E.U.-approved biosimilar versions of rHuEPO with the originator product have concluded that they were structurally similar.¹⁴ To avoid confusion, products that have not undergone rigorous evaluation of their similarity to the reference biologic with respect to structure, function, and nonclinical and clinical properties should not be referred to as biosimilars.

More recently, many developing countries have participated in discussions leading to the WHO guidelines on similar biopharmaceutical products, thus suggesting that they may adopt similar standards for approval fashioned on the WHO guidelines. Recently, the Korea FDA approved Remsima (Celltrion), a biosimilar version of Remicade (infliximab, Janssen). Although the full package submitted for approval is unknown, the sponsor conducted head-to-head studies against infliximab in the RA and ankylosing spondylitis populations consistent with the WHO guidelines. These studies showed generally similar response rates as the reference biologic.^{15,16}

IMPLICATIONS FOR HEALTH CARE PROVIDERS

Now that the United States has passed enabling legislation allowing an abbreviated path to approval of biosimilar products, it is only a matter of time before biosimilars appear in the marketplace. Given the prominent place of biologics in the armamentarium of rheumatologists, this will have an important impact in rheumatology. What do rheumatologists need to know about biosimilars to make sound, thoughtful decisions? Foremost in the mind of practicing physicians is knowing that they can count on the

safety profile and efficacy of products that they prescribe. In that regard the FDA has signaled that any biosimilar that appears on the market in the United States will have been rigorously tested side by side the innovator product as noted earlier.

State pharmacy laws have not yet been revised to address when automatic substitution of biosimilars for their reference products is permissible. Caution is warranted before permitting automatic substitution. The FDA has indicated that additional studies will be required for a biosimilar to be deemed interchangeable. Studies will need to be conducted to demonstrate that the outcome of switching to a biosimilar from the innovator and back is similar to what patients would have experienced if they had kept taking the innovator product. Particularly important in this regard is a demonstration that switching does not lead to greater immunogenicity than staying with the reference product does.

The introduction of biologics in the last decade has revolutionized clinical practice in rheumatology by allowing effective control of disease in many patients who had inadequate treatments available previously. Nonetheless, many patients who could benefit from biologics could not receive them because of their high price. Physicians are looking to biosimilars for a cost-effective alternative to the innovator molecules to allow more widespread access. The new legislation has provisions to continue to reward innovation for products that address unmet medical need while providing a path forward for products to be approved as biosimilars that meet the FDA standards for similar safety and efficacy. Knowledge of the process for assessing biosimilars and key differences between biosimilars and generic small-molecule drugs will allow physicians to determine when a biosimilar may be right for their patients.

Infections and biologic therapy for rheumatoid arthritis: an update on risk and prevention

■ KEVIN L. WINTHROP

- Patients with rheumatoid arthritis are at higher risk for infection because of disease and immunosuppressive therapies, including prednisone, biologics, and tofacitinib.
- The increased risk associated with biologics can be mitigated, however, when these agents improve control of disease and lead to reductions in prednisone use.
- At present, most biologics appear to be similar in their propensity to promote serious infection. Certain exceptions exist with regard to specific organisms (e.g., granulomatous pathogens) and specific therapies based on mechanism of action.
- Prevention of infection by screening and vaccination is an evolving strategy that serves to further mitigate risk.

RHEUMATOID ARTHRITIS AND BURDEN OF INFECTION

It is well known that patients with rheumatoid arthritis (RA) suffer greater morbidity and mortality from infectious diseases.¹⁻³ Although some of this increased burden is attributable to the immunosuppressive therapies used to treat RA (the focus of this chapter), it is likely that the underlying immune derangements of RA itself are also in part responsible.^{4,5} This immune system dysregulation potentially explains the nearly twofold increase in hospitalized infections observed in patients with RA, a risk that exists independent of immunosuppressive therapy. This was well documented during the prebiologic therapy era in the Mayo Clinic population when Doran and colleagues⁶ observed a hospitalized infection rate of 9 per 100 patient-years for RA patients and a clear elevated relative risk for pneumonia, skin and soft tissue infection, and bone and joint infection as compared with patients without RA. Importantly, these risks were independent of corticosteroid or other disease-modifying antirheumatic drug (DMARD) therapies in use at the time. Now, more than a decade later, the introduction and widespread use of biologic therapy have intensified the assessment of infection risk and prevention in the setting of RA, and although many unknowns still exist, our understanding of the infectious risk associated with these agents is more complete than ever, even as it continues to evolve over time.

PREDNISONE

There is little debate regarding corticosteroid's ability to cause infectious harm. Admittedly, clinical trial data with glucocorticoids do not support this perception,⁷ but data from observational studies ("real-world" populations) clearly and repeatedly suggest a dose-dependent elevated risk for hospitalized infections. The majority of studies suggest that patients taking prednisone have a 1.5- to 3-fold increased risk for serious infection.⁶⁻⁸ This increased risk has been noted even at doses considered "low."

In the United States, a 2006 study using the National Databank for Rheumatic Disease observed a nearly 1.5-fold elevation in risk for hospitalized infection even at doses lower than 5 mg/day.⁸ Other subsequent studies using registry, claims, and administrative data have found similar levels of

increased risk at doses of 5 mg or lower, as well as higher risk at higher doses in some cases.⁹⁻¹⁷

This includes a recent U.S. study that combined Medicare, Medicaid, health maintenance organization, and health plan administrative data (the Safety Assessment for Biologic thERapy [SABER] study) to form a cohort of more than 100,000 RA patients. Within this cohort, analysis of patients restricted to those starting new DMARDs and controlled for differences in RA disease severity and comorbidity (n = 10,000 RA patients included in the analysis) also found increased risk at prednisone doses lower than 5 mg and a nearly threefold elevated risk at average doses higher than 10 mg/day (Table 67.1).¹⁵

Similarly, other North American population-based studies report similar elevations in risk at doses lower than 5 mg and up to a fivefold higher risk when average doses of 20 mg or greater were studied.^{12,14} In Europe, observational studies report much the same. The German biologic registry for RA patients (Rheumatoid Arthritis oBservatiOn of Biologic Therapy, or RABBIT) identified an elevated relative risk for serious infection of between twofold and fivefold, depending on the average daily steroid dose, with the British Biologics registry documenting similar findings.^{16,18} Beyond bacterial infections, corticosteroids also raise the risk for opportunistic infections.¹⁹⁻²⁵ Similar to bacterial infections, these risks are dose dependent. Despite these infectious risks and the advent of newer biologic therapies, corticosteroid use in patients with RA remains common.²⁶

BIOLOGIC THERAPIES AND RISK FOR INFECTION

Our understanding of the relative infectious risks posed by biologic therapy is a moving target. Estimates of risk vary according to the type of study conducted (e.g., randomized controlled trials [RCTs] generally reveal lower risk than long-term extension studies do), and with time it is likely that patients and physicians have "learned" to use such therapies better (i.e., in safer fashion) such that more recent studies might not be comparable to those from earlier periods. Furthermore, it is clear that much of the variability in an individual's risk for infection is attributable to patient factors (e.g., age, chronic lung disease, and other comorbid conditions) and not necessarily the therapies (Fig. 67.1).^{12,16} In addition, biologic therapies can serve as corticosteroid-sparing agents and improve disease control (thereby lowering risk), and it can be difficult to estimate or model how infectious risk changes after treatment with a particular biologic is started. Despite these challenges, some general comments can be made. For anti-tumor necrosis factor (TNF) therapies, higher absolute infection rates among anti-TNF users have generally been observed, particularly in the first few months after initiation of drug therapy. Fairly similar rates of serious infection have been reported in clinical trials of different anti-TNF compounds, although not unexpectedly, absolute infection rates for these compounds observed in the "real-world" setting of population-based observational studies are typically higher than those reported from clinical trials. For the more recently approved classes of biologics for RA (i.e., abatacept, tocilizumab, rituximab) and for tofacitinib, rates of serious infection observed in clinical trials have largely been similar to those observed in anti-TNF trials. However, how these drugs behave in nonclinical trial populations is currently unknown. Population-based infection rates and risk estimates are largely missing because such observational registry or database studies of these therapies are still lacking for the most part.

TABLE 67.1

Dose-dependent increase in hospitalized infection rates observed with glucocorticoid use from the Safety Assessment for Biologic tHERapy (SABER) study, United States

Exposure	Events (No.)	Person-years (No.)	Rate per 100 person-years	Hazard ratio (95% CI) for propensity score–matched cohorts	Adjusted hazard ratio (95% CI)
Rheumatoid arthritis					
Nonbiologic regimens	326	4192	7.78	1	1
TNF- α antagonists	497	6089	8.16	1.05 (0.91-1.21)	1.05 (0.91-1.21)
Baseline glucocorticoid use, prednisone equivalents					
None					1
>0 to <5 mg/day					1.32 (1.10-1.58)
5 to 10 mg/day					1.78 (1.47-2.15)
>10 mg/day					2.95 (2.41-3.61)

CI, confidence interval; TNF, tumor necrosis factor.

Fig. 67.1 Additional risk factors are one or two of the following: age older than 60 years, chronic lung disease, chronic renal disease, or higher number of treatment failures; three risk factors: two of the above risk factors plus previous serious infection. DMARD, disease-modifying antirheumatic drug; TNFi, tumor necrosis factor inhibitor. (From Strangfeld A, Eveslage M, Schneider M, et al. Treatment benefit or survival of the fittest: what drives the time-dependent decrease in serious infection rates under TNF inhibition and what does this imply for the individual patient? *Ann Rheum Dis* 2011;70:1914-20.)

TUMOR NECROSIS FACTOR ANTAGONISTS AND RISK FOR INFECTION

As a group, anti-TNF therapies (etanercept, adalimumab, infliximab, golimumab, certolizumab) inhibit TNF- α , a cytokine expressed by activated macrophages and other immune cells that is known to play a crucial role in the host response to a variety of infections.²² The importance of TNF has been demonstrated in *in vitro*, animal, and human studies with a variety of organisms, and it is involved in the host response to both intracellular (e.g., *Mycobacterium tuberculosis* and fungi) and extracellular organisms (e.g., *Klebsiella pneumoniae* and *Streptococcus pneumoniae*).²⁷⁻³³

Not surprisingly, risk for infection is elevated with the use of these compounds; however, as discussed, precise infectious risks attributable to anti-TNF therapy are in some cases difficult to quantify. The results from meta-analyses of TNF antagonist trials are mixed. Although rates of serious infection are generally higher in biologic-treated patients, the relative risks observed in comparison to placebo are frequently small and not statistically

significant. Bongartz and coworkers³⁴ analyzed monoclonal antibody trials (infliximab and adalimumab only) in patients with RA and observed a twofold increase in risk for serious infection, whereas another meta-analysis that included etanercept, infliximab, and adalimumab found no statistically increased risk (relative risk, 1.08 [0.81 to 1.43]) in those treated with anti-TNF therapy versus placebo.³⁵ Interestingly, this study did reveal a significant twofold elevation in risk in studies using higher doses of infliximab or adalimumab. A recent Cochrane review of all TNF antagonists across disease indications found only infliximab (odds ratio [OR], 1.45 [0.99 to 2.1]) and certolizumab (OR, 3.5 [1.6 to 7.8]) to be associated with elevated risk for serious infection in comparison to placebo.³⁶ Taken together, these studies might imply a somewhat higher risk for some TNF antagonists. However, there are severe limitations in relying on such studies to understand the infection profiles of these drugs (e.g., low statistical power for individual trials, careful selection of patients for RCTs) and even greater difficulty in comparing drugs across trials (e.g., differences in inclusion criteria, populations, disease indications).

Because of these shortcomings and given the need for long-term monitoring of safety, a number of biologic treatment registries have been created in Europe, North America, and Japan from which cohort studies can be conducted. In addition, large, population-based, observational studies using health plan or administrative claims data have also assessed the risk for infection with these compounds. Even though such studies also have limitations (e.g., confounding by indication), a number of these studies have used sophisticated analyses (i.e., propensity scores) in an attempt to control for underlying and potentially confounding differences between patients who receive biologic DMARDs and those who receive nonbiologic DMARDs. Despite some heterogeneity in methods, these studies have typically reported somewhat similar estimates of serious infection in patients treated with anti-TNF therapies, typically between 3 and 8 per 100 patient-years (Table 67.2). Some of these studies show a higher and significantly elevated risk soon after initiation of TNF antagonist therapy that declines after 3 to 6 months of use, such that relative risk estimates are much lower when longer periods are assessed.^{11,12,13,37} Reasons for this decrease in risk are multifactorial and probably include a “survivor effect” (i.e., individuals in whom infection is more likely to develop become infected sooner and are censored), as well as improvements in RA disease activity and changes in concomitant therapies such as steroid reduction after commencement of biologic therapy.¹⁶ Several other large recent studies have produced conflicting results, although differences in their methodologies are worth noting. The aforementioned population-based SABER study from the United States¹⁵ was somewhat unique in that it compared only new users of anti-TNF therapy with new users of nonbiologic DMARDs. This comparison was made in a very specific setting because the patients starting treatment with a nonbiologic DMARD were already being treated with methotrexate (and presumably failing, hence the need for additional therapy). Accordingly, the study effectively compared RA patients starting infliximab, etanercept, or adalimumab therapy with similar patients (in terms of underlying disease severity and comorbid conditions) who started hydroxychloroquine, leflunomide, or sulfasalazine therapy after or during methotrexate use. A high rate of serious infections (8/100 patient-years) was seen in the RA population overall, but no increase in risk was observed in those starting TNF antagonists, including during the few months after initiation of drug therapy

TABLE 67.2

The biologic era: rates and relative risk for serious infections in patients with rheumatoid arthritis treated with anti-TNF therapy from European and North American observational cohort studies

Country/year	Crude incidence per 100 patient-years		Adjusted RR* (95% CI)
	Treated with anti-TNF	Nonbiologic comparator	
Germany, 2005	6.4, ETN 6.2, INF	2.3	2.2 (0.9-5.4), ETN 2.1 (0.8-5.5), INF
UK, 2007	5.5	3.9	1.3 (0.9-1.8) [†] 4.6 (1.8-11.9) [‡]

[‡]Adjusted relative rate when not restricted to the first 90 days of therapy.

[§]Analysis restricted to the first 6 months after initiation of anti-TNF therapy.

^{||}Rate calculated at 1 year after starting treatment and adjusted for RA severity and comorbid conditions associated with infections.

[¶]Adjustment for time-varying risk factors, treatment adaptations, and dropout.

*Rate up to 1 year after starting drug therapy.

CI, confidence interval; ETN, etanercept; INF, infliximab; NR, not reported; RR, relative risk; TNF, tumor necrosis factor.

(see Table 67.2). The study also reported slightly higher and statistically significant infection rates in those who start infliximab therapy relative to those starting etanercept or adalimumab (rates were approximately 25% higher). However, infliximab users were more likely to be prescribed methotrexate after initiation of drug therapy than were those starting either etanercept or adalimumab, and it is unclear whether this could have contributed to the observed difference in risk. Other population-based studies have failed to find a similar increase in relative risk for bacterial infections with the use of infliximab as compared with other TNF blockers.^{10,37,38} The SABER study produced a number of subanalyses, and even though no increased risk with initiation of TNF antagonist therapy could be demonstrated in any of the inflammatory disease groups (patients with inflammatory bowel disease, psoriasis, and ankylosing spondylitis were also studied) or in stratified analyses, the study reiterated the importance of patient comorbidity and age to the risk for infection. For example, anti-TNF-treated patients with a history of chronic obstructive lung disease (COPD) had rates of serious infection of nearly 17 per 100 patient-years versus 7 per 100-patient years in those without COPD.

Taken together, these and other observational studies suggest that the net infectious risk associated with biologic therapy is neither straightforward to understand nor easy to calculate. To date, only one observational study has accounted for changes in disease activity and concomitant therapies that take place after starting biologic or nonbiologic comparator therapy. The RABBIT registry reported that anti-TNF therapy improved disease control and decreased prednisone use, both of which lower the risk for infection, but that even when controlling for these changes after initiation of drug treatment, anti-TNF therapy significantly increased the risk for serious infections 1.8-fold (see Fig. 67.1).¹⁶

Opportunistic infections with anti-tumor necrosis factor therapy

Since the early clinical trials, a number of intracellular infections have been reported in this setting, including infections with *M. tuberculosis*, nontuberculous mycobacteria (NTM), *Pneumocystis*, *Histoplasma*, *Coccidioides*, *Listeria*, *Salmonella*, and others.³⁹ Tuberculosis (TB) is most clearly associated with TNF blockade and has been reported with all five TNF antagonists.

TABLE 67.3

The biologic era: rates and relative risks of opportunistic infections in patients with rheumatoid arthritis treated with anti-TNF therapy from European and North American observational cohort studies

Country/year	Outcome studied	Crude incidence per 100,000 patient-years		Adjusted RR* (95% CI)
		Treated with anti-TNF	Nonbiologic comparator

However, in population-based studies in which drug-specific risks have been studied, a clear distinction in risk can be made between the fusion receptor construct etanercept and the monoclonal antibodies infliximab and adalimumab. Although each of these drugs is associated with elevated risk for TB, the incidence of TB is threefold to fourfold higher in infliximab- and adalimumab-treated subjects than in those treated with etanercept.^{40,41} Animal and *in vitro* studies have provided potential explanations for this difference in risk, including differential downregulation of antigen-stimulated interferon- γ (IFN- γ), differential effects on antimicrobial-producing CD8 effector cells, and poorer penetration of the granuloma by etanercept.⁴²⁻⁴⁴ Even though TB has been reported in clinical trials of certolizumab and golimumab, population studies evaluating their relative risk for TB with the other TNF blockers have not yet been done.

The risk for TB with anti-TNF therapy not surprisingly varies according to the background prevalence of TB in the regional population, and risk estimates also vary according to when the studies were conducted. Early population-based studies conducted in low-prevalence TB regions and prior to the widespread introduction of screening for TB before initiation of biologic DMARD therapy generally reported rates of TB that were 5 to 20 times higher than in the background general populations, including early studies from the United States (incidence of 52/100,000) and Sweden (incidence of 118/100,000).^{45,46} In Spain, where background rates of TB are low (but severalfold higher than in the United States), investigators reported an incidence of TNF antagonist-associated TB of 1900 per 100,000 person-years, a rate that was 10 to 20 times higher than that found in RA patients not using anti-TNF therapy. After the subsequent widespread introduction of screening for TB before the use of biologics, Spanish investigators noted a dramatic decrease in the anti-TNF-associated incidence of TB.⁴⁷ The most recent observational studies conducted in the United States and Western Europe all document an elevated incidence of TB with anti-TNF therapy relative to either the general public or RA patients treated with nonbiologic DMARDs (Table 67.3).^{41,48-50} Furthermore, at least in the United States (and probably in other regions with low TB endemicity), disease with NTM is more prevalent than TB in the anti-TNF setting.^{41,51} Pulmonary NTM disease is probably also associated with RA independent of immunosuppressive therapy. These environmental organisms (most commonly *Mycobacterium avium* complex) are more likely to infect middle-aged and elderly

individuals, particularly women and those with chronic underlying lung disease.⁴¹ Finally, like TB, extrapulmonary manifestations of disease with NTM appear to be more common in patients treated with anti-TNF therapy.⁵²

For some other types of opportunistic infection, the overall picture is that anti-TNF therapy does increase risk, particularly those that involve granulomatous host responses. The risk for endemic mycosis (histoplasmosis, coccidioidomycosis, blastomycosis) varies according to geography and baseline risk. For some “opportunistic” infections that do not involve granulomatous responses, the question of risk is less clear. Reactivation of varicella zoster (i.e., shingles) is clearly the most common “opportunistic” infection in the anti-TNF setting because it occurs more frequently in RA patients (than in patients without RA) and its risk increases with advancing age. Risk for shingles is clearly elevated 1.5- to 2-fold with the use of prednisone, but studies assessing its relationship with anti-TNF therapy have produced conflicting results.²² Investigators from the German and British biologic registries have documented a small elevated risk with anti-TNF therapy; however, two large population-based studies in the United States found no increased risk with anti-TNF therapy (see Table 67.3).^{24,53-55} Together, these studies do suggest, however, that patients in whom shingles develops while being treated with TNF antagonists are no more likely to have disseminated or complicated zoster than patients in whom shingles develops while using nonbiologic DMARDs.^{22,24,53}

Abatacept, rituximab, tocilizumab, and anakinra

Given the mechanism of action of these biologics, a variety of related infections could be hypothesized. To date, RCT and open-label experience with these compounds has produced similar infection profiles as those with anti-TNF agents, though with some notable exceptions. Full understanding of their safety profiles still awaits further study since postmarketing experience and observational data are relatively recent with these compounds.

Risk for serious bacterial and opportunistic infections

Clinical trials of rituximab in patients with RA did not suggest a significantly increased risk for serious infection,⁵⁶ although further experience in long-term extension studies highlighted small subgroups of patients in whom persistently low IgG levels develop after rituximab treatment and who are at increased risk for serious infection.^{57,58} One observational study using administrative data evaluated hospitalized infection risk in TNF antagonist “failures” (i.e., patients switching to another biologic). The study observed higher rates of hospitalized infection rates in patients switching to rituximab versus other biologics, but after adjusting for other risk factors for infection, the risk was similar to that in those switching to etanercept, adalimumab, and abatacept (and significantly lower than in those switching to infliximab).⁵⁹ Limited data have been published with regard to opportunistic infections and rituximab. Mycobacterial case reports (both TB and NTM) exist for patients treated with rituximab, although these patients have also been taking methotrexate and prednisone.^{54,60} With regard to viral infection, rituximab clearly promotes the progression of chronic hepatitis B virus (HBV) infection, and its use should be avoided in such patients.^{36,61,62}

Progressive multifocal leukoencephalopathy (PML) has been reported in RA patients treated with biologics, including rituximab. Outside the human immunodeficiency virus setting, PML is quite rare and its incidence in patients with RA is 1 per 1,000,000.⁶³ To date, the U.S. Food and Drug Administration (FDA) has received reports of 14 cases of PML in patients treated with rituximab for autoimmune inflammatory diseases; however, only 1 of these patients lacked other risk factors for PML, and 10 were using other immunosuppressive therapies concomitantly.⁶⁴ The contribution of rituximab to the development of PML remains unknown, however, and reassuringly, the condition is quite rare in RA patients regardless of their therapy.

For abatacept, a small increased risk for serious infection was observed during clinical trials in some subsets of patients (e.g., those with COPD), and in those treated concomitantly with anti-TNF therapy, the incidence of serious infections was significantly elevated (such concomitant therapy was subsequently contraindicated).⁶⁵⁻⁶⁸ Meta-analyses of RCT and open-label extension data documented rates of hospitalized infection of 2.7 per 100 patient-years in patients treated with abatacept.⁶⁹ Opportunistic infections have also been reported, although their relative risk remains unknown. TB occurred at a rate of 60 per 100,000 patient-years in abatacept RA trials, but it is unknown how this compares with the background risk for TB in these populations, and patients were screened for latent TB before entry into these trials.⁶⁹ In animal studies, abatacept does not appear to negatively affect the immune system of mice who are exposed to TB.⁷⁰ At least one randomized trial has compared the efficacy and safety of abatacept with that of infliximab; at 1 year patients taking abatacept suffered significantly fewer serious infections than did infliximab-treated patients (1.9% versus 8.5%). No cases

of opportunistic infection were seen in the abatacept-treated group, whereas five such cases were seen in the infliximab group, including two cases of TB and one of *Pneumocystis jiroveci* pneumonia.⁷¹

For the interleukin-6 (IL-6) receptor antagonist tocilizumab, RCTs and long-term extension trials have revealed rates of serious infection of 4.9 per 100 patient-years in patients receiving 8 mg/kg, whereas lower rates (3.5/100 patient-years) were observed in those receiving placebo or low-dose tocilizumab.⁷² Population-based observational data are only now beginning to emerge, with one study recently published from Japan where this compound has been in use for a relatively longer period. Within their tocilizumab postmarketing surveillance program (N = 3881 patients), they observed a rate of serious infection of 9 per 100 patient-years. With regard to opportunistic infections, shingles occurred at a frequency of 6.1 cases per 1000 patient-years, and 4 TB cases were reported (incidence rate of 220/100,000 person-years). This TB rate is similar to that observed in the postmarketing experience for anti-TNF therapies in Japan, although the rate is 10-fold higher than that in the background Japanese population.⁷³

Tofacitinib

Few data have been published in the peer-reviewed literature on the infectious risk associated with tofacitinib, a recently FDA-approved small molecule that inhibits Janus activating kinases 1 and 3 (JAK1/3). *In vitro*, this drug has been shown to diminish CD4+ T-lymphocyte production of INF- γ and IL-17.⁷⁴ Rates of serious infection were reported in several published phase 3 studies, and they were similar to those seen in RCTs of biologics. Rates of shingles, however, were elevated in tofacitinib-treated patients in RCTs and long-term extensions trials, particularly within Asian regions, and higher than those observed in other studies of TNF antagonists.⁷⁵⁻⁷⁷ TB cases occurred infrequently during clinical trials, though more frequently in patients receiving higher tofacitinib doses and in countries with a higher prevalence of TB. Patients were screened and, when indicated, started treatment of latent TB infection before study entry.⁷⁸

Prevention of infection in patients treated with biologics (screening and vaccination)

The serious infections most common in the setting of biologic therapy and in patients with RA in general are skin and soft tissue infections and community-acquired pneumonia.^{8,10,79} Like skin and soft tissue infections within the general public, most are probably due to *Staphylococcus aureus* and *Streptococcus* species.⁸⁰ For community-acquired pneumonia, these infections are also probably due to the same organisms that cause pneumonia in general populations, and *S. pneumoniae*, *Haemophilus influenzae*, *S. aureus*, gram-negative bacilli, and influenza are among the most common causative pathogens.⁸¹ Strategies to reduce the risk for hospitalized pneumonia include both pneumococcal and influenza vaccination. Historically, the 23-valent pneumococcal vaccine (PPSV-23) [Pneumovax] has been used and recommended before initiating anti-TNF and other long-term immunosuppressive therapies, including methotrexate (primarily for protection against invasive pneumococcal disease).⁸² Immunogenicity to this vaccine is poor and diminished by methotrexate, as well as by some other biologic drugs (e.g., rituximab), but it is relatively unaffected by anti-TNF therapy.⁸³ The FDA has recently approved the new 13-valent conjugate pneumococcal vaccine (PCV-13) for use in adults, a vaccine that should theoretically provide longer and improved protection against pneumococcal disease than PPSV-23 does.⁸⁴ Currently, however, no data are available on whether PCV-13 produces more robust immune responses than PPSV-23 does in patients being treated with biologic or nonbiologic DMARDs. It is currently recommended, however, that PCV-13 be administered to all adults with immunocompromising conditions, including RA. Current data suggest that a vaccine strategy that begins with PCV-13 and then follows with a PPSV-23 booster provides higher levels of antibodies to pneumococcal serotypes, at least in the first year after the booster.⁸⁵

Intramuscular influenza vaccination should be given yearly to all patients with RA (except those with a history of anaphylaxis to egg products), and the vaccine generally provides effective immune responses even when administered during biologic therapy (with the exception of rituximab, which severely diminishes such responses).^{86,87}

Intracellular pathogens

TB is perhaps the opportunistic infection that is most clearly preventable in the setting of biologic therapy. Screening recommendations for latent TB infection before initiation of biologic therapy have been issued by a wide variety of professional societies and public health entities.^{26,36,88,89} In the last

5 years, more recommendations have incorporated the use of IFN- γ release assays (IGRAs), Quantiferon-Gold TB In-tube® (QFT-IT), or the T-SPOT. TB®, which have improved specificity for TB relative to the tuberculin skin test (TST). This is of particular relevance in patients with a history of bacille Calmette-Guérin (BCG) immunization, in whom the TST is less preferred because of the known ability of BCG to cause false-positive TST responses. However, current data suggest that neither IGRAs nor the TST alone sufficiently identifies all infected patients because false-negative results can occur with either test, particularly in immunosuppressed individuals.⁹⁰ A strategy that uses both tests (or in the case of a BCG-vaccinated individual, a dual IGRA strategy) is probably warranted, particularly in patients with risk factors for TB.

For NTM and fungal disease, there is little in the way of preventive tools for the clinician to use other than ruling out active infection before starting drug therapy. Pulmonary NTM has emerged as an infection with a predilection for RA patients, and presumably some of these patients are identified during screening for TB.^{41,91} Patients with chronic, unexplained cough or those with abnormalities on their baseline chest radiographs should undergo further workup (potentially including chest computed tomography, culture of respiratory specimens as appropriate, or both) before starting biologic therapy.⁹² For fungal disease with *Histoplasma* and *Coccidioides*, no clear utility of serologic or other screening before biologic therapy has emerged.

Geographically, the epidemiology of HBV closely mirrors that of TB, with similar regions of high prevalence around the world. Unlike hepatitis C virus, for which anti-TNF compounds appear to be relatively safe, HBV progression can occur in patients using anti-TNF therapy. Accordingly, all patients should be screened for HBV before using such therapies. In addition to evaluating hepatitis B serum antigen status (a marker of active infection), both core antibody and surface antibody evaluations should be conducted.⁹³ Furthermore, in patients who have evidence of previous infection (i.e., positive hepatitis B core antibody), HBV DNA should be checked before starting biologic therapy and thereafter at periodic intervals. For patients with active HBV, TNF antagonist therapy has been used safely with concomitant antiviral therapy in the context of close laboratory and clinical monitoring.^{93,94} For other biologics, there is less experience in patients with active HBV

infection. Several cases of HBV progression have been reported in patients taking abatacept and not being treated with concomitant antiviral therapy (and several patients were treated safely with concomitant antiviral therapy), and several patients with HBV have successfully used tocilizumab in the context of antiviral prophylaxis.⁹⁴ Rituximab, however, remains contraindicated in such patients because poor outcomes and death have been reported in those with active HBV infection.

Shingles remains a vaccine-preventable disease in patients with RA treated with biologic therapy, and it is clear that these patients suffer greater shingles morbidity, thus making them ideal candidates for vaccination. The vaccine Zostavax® is licensed for the prevention of shingles in patients older than 50 years and has been shown to reduce overall risk for zoster by 67% in those vaccinated.⁹⁵ However, because of the theoretic safety concerns associated with a live vaccine, it is currently contraindicated in those taking biologic therapy, which makes it difficult to vaccinate many RA patients. Given the high morbidity and prevalence of this disease in RA and the inability to currently vaccinate RA patients treated with biologic agents, effort should be made to evaluate the safety and efficacy of this vaccine in this context.

CONCLUSION

Patients with RA are at higher risk for serious infection and death from infection than the general public is. Prednisone and biologic agents increase this risk, although such risk can be mitigated when biologic agents act as prednisone-sparing therapies. Some of the important causes of infectious morbidity in this setting are preventable with screening (i.e., TB) or vaccination (i.e., herpes zoster).

Acknowledgments

The author warmly thanks Jennifer Ku for supporting the development of this chapter by assisting with literature search and formatting of the manuscript.

Drugs and pregnancy

■ BONNIE LEE BERMAS

- Pregnancy impacts each rheumatic disease differently.
- If possible, patients with inflammatory arthritis and systemic rheumatic diseases should have the disease under good control before conception.
- Patients who have preexisting renal disease, in the context of either systemic lupus erythematosus or another collagen vascular disease, should be in remission for 6 months before conception.
- Clinicians should not empirically treat diagnoses or a laboratory test result but rather treat symptoms and signs of active disease.
- Aspirin can be used throughout pregnancy and other nonsteroidal antiinflammatory drugs can be used from the time of implantation until the last trimester of pregnancy.
- Glucocorticoids can be used during pregnancy for disease flares. There is about a threefold increased risk of cleft palate formation in fetuses exposed to glucocorticoids during the first trimester. Maternal risks of the use of these medications later in pregnancy include glucose intolerance, hypertension, and osteoporosis.
- Antimalarials, sulfasalazine, azathioprine, and cyclosporine can be used during pregnancy.
- Gold, cyclophosphamide, methotrexate, and leflunomide should be avoided during pregnancy.
- Data on the use of anti-tumor necrosis factor therapy during pregnancy are limited, although evidence suggests that these medications may be used in some circumstances.
- Clinicians should review the potential toxicities of medications during pregnancy with patients before initiating therapy.

Rheumatologic disorders occur commonly in women during their reproductive years. Thus clinicians should be familiar with how to manage rheumatic diseases during pregnancy. The impact of a pregnancy on the mother's disease activity, coupled with the potential toxicity of many anti-rheumatic medications to both mother and fetus, make treatment challenging. Data on the potential toxicity of a particular pharmacologic agent are often limited. Commonly, we rely on animal studies that use superpharmacologic dosing to evaluate a drug for teratogenicity. Alternatively, we refer to case reports of drug exposure in a handful of pregnancies. Neither of these approaches adequately reveals the true risk of a particular therapy during pregnancy. The U.S. Food and Drug Administration (FDA) use-in-pregnancy ratings are likewise based on limited information (Box 68.1). The American College of Rheumatology last addressed this issue in its guidelines for monitoring drug therapy in rheumatoid arthritis (RA) published in 1996.¹ Since then, both the management of disease and our experience with commonly used medications during pregnancy has changed. This chapter discusses the treatment of the pregnant patient with a rheumatic disorder with special emphasis on medication safety during pregnancy and nursing. Medications reviewed in this chapter include aspirin and other nonsteroidal antiinflammatory drugs, glucocorticoids, antimalarials, gold salts, immunosuppressive agents, antimetabolites, cytotoxic agents, intravenous immune globulin, and biologics (Table 68.1). Treatment recommendations and approaches to patient care are described wherever possible.

PREGNANCY

For a pregnancy to be successful, the mother must tolerate the fetus, which is a hemi-allograft. Some theories of what happens to the immune system during pregnancy to promote fetal survival include expression of nonclassical major histocompatibility complex class I by the trophoblast and the attenuation of natural killer cell activity.² Recent murine data suggest that suppression of the maternal response to paternal alloantigens by extrathymic regulatory T cells also plays an important role in pregnancy immunology.³

Rheumatic diseases and pregnancy

Changes in the immune system during pregnancy may modify the disease activity of different rheumatic diseases in disparate ways (Table 68.2). Conventional wisdom is that up to 70% of patients with RA experience remission when pregnant.⁴ However, newer evidence suggests that the actual number of patients who improve during pregnancy may be closer to 50%.⁵ Why this amelioration of symptoms occurs is unclear, but it may be related to some of the alterations in inflammatory cytokine levels that are observed during pregnancy. For example, tumor necrosis factor- α and other cytokines are down-regulated during pregnancy,⁶ and this may have a positive impact on disease activity in RA.⁷

In contrast to the data for RA, the data for systemic lupus erythematosus (SLE) are unclear. Some studies suggest that SLE is not impacted by pregnancy, whereas other studies suggest that SLE is exacerbated by pregnancy.^{8,9} There is even more limited information regarding other rheumatologic disorders. Therefore the clinician may not be able to predict which patient with a rheumatic condition is likely to experience a flare during pregnancy.

There are several guiding principles in managing patients with rheumatic diseases during pregnancy (Box 68.2). First, the patient should be in clinical remission or have her disease under good control at the time of conception. Specifically, in patients who have lupus nephritis or another rheumatologic disorder with renal involvement, the kidney disease should be in remission for at least 6 months before conception. This approach should also be applied to those patients that have other significant organ involvement as part of their rheumatologic disease. Second, patients should be following a therapeutic regimen that can be continued during pregnancy. For example, in patients with RA, if the disease is under good control, one can consider discontinuing medications before pregnancy. On the other hand, in those patients with active disease, it may be prudent to continue their medications that are considered compatible with pregnancy. Third, the clinician should treat active disease symptoms and signs and not a clinical diagnosis or a laboratory test result. Thus there is no role for empirical immunosuppression in pregnant patients with rheumatologic disorder who are in clinically stable condition.

ASPIRIN, OTHER NONSTEROIDAL ANTIINFLAMMATORY DRUGS, AND CYCLOOXYGENASE-2 INHIBITORS

Aspirin, other nonsteroidal antiinflammatory drugs (NSAIDs), and the cyclooxygenase-2 (COX-2) inhibitors are the cornerstones of treatment for the pain and joint inflammation in arthritic conditions. In humans, exposure to high-dose aspirin *in utero* during 5128 pregnancies did not result in an increased rate of fetal malformation despite reports that high-dose aspirin exposure in animals can be teratogenic.^{10,11} Furthermore,

BOX 68.1 FOOD AND DRUG ADMINISTRATION USE-IN-PREGNANCY RATINGS

- A Controlled studies show no risk. Adequate, well-controlled studies in pregnant women have failed to demonstrate risk to the fetus.
- B No evidence of risk in humans. Either animal findings show risk but human findings do not, or, if no adequate human studies have been performed, animal findings are negative.
- C Risk cannot be ruled out. Human studies are lacking and results of animal studies are either positive for fetal risk or lacking as well. However, potential benefits may justify the potential risk.
- D Positive evidence of risk. Investigational or postmarketing data show risk to the fetus. Nevertheless, potential benefits may outweigh the potential risk.
- X Contraindicated in pregnancy. Studies in animals or humans, or investigational or postmarketing reports, have shown fetal risk that clearly outweighs any possible benefit to the patient.

BOX 68.2 TREATMENT PRINCIPLES FOR PATIENTS WITH RHEUMATIC DISEASES DURING PREGNANCY

- Disease should be in remission or under good control at the time of conception.
- Medications should be minimized or discontinued as appropriate.
- The disease symptoms, not the diagnosis, should be treated (e.g., a patient with systemic lupus erythematosus does not need empirical steroid therapy during pregnancy unless the disease is active).

low-dose aspirin is part of the treatment regimen for pregnant women with antiphospholipid syndrome and obstetric complications.¹² The American Academy of Pediatrics concludes that aspirin is compatible with breastfeeding.¹³

In animals, high doses of some NSAIDs are teratogenic.¹⁴ In humans, NSAIDs do not cause fetal malformations but can cause premature closure of the ductus arteriosus when used during the third trimester.¹⁵ Therefore one can treat with NSAIDs during the first two trimesters of pregnancy, but these medications need to be discontinued during the third trimester. The American Academy of Pediatrics considers most NSAIDs to be compatible with breastfeeding.¹³

Data on the use of the newer COX-2 inhibitors during pregnancy are limited. To date, there are no reports of fetal malformations after exposure to these drugs *in utero*; however, there are insufficient data in humans to evaluate their safety during pregnancy. In animal studies COX-2 inhibitors can interfere with both ovulation and implantation.¹⁶ Because NSAIDs have both COX-1 and COX-2 inhibitory effects, patients should discontinue both NSAIDs and COX-2 inhibitors at the beginning of a menstrual cycle in which they plan to try to conceive. No data are available on the safety of the COX-2 inhibitors in breastfeeding mothers.

Aspirin and other NSAIDs can be used during the pregnancy. The NSAID should be discontinued during the third trimester, and both NSAIDs and COX-2 inhibitors should be held during a conception cycle.

GLUCOCORTICOIDS

Glucocorticoids are used to treat many rheumatologic disorders. Prednisone and prednisolone, the forms most commonly used in rheumatology, are not readily metabolized by the placenta and reach the fetus in low concentrations. In contrast, betamethasone and dexamethasone, the fluorinated glucocorticoids, reach the fetus at higher concentrations and can be used for treating fetal conditions such as lung immaturity.¹⁷ In animals, glucocorticoids have been shown to increase aggressive behavior in the mother and increase the incidence of cleft palate formation.^{18,19} In humans the data are more reassuring. In a large series of asthma patients who were treated with glucocorticoids (mean dose, 8 mg/day) during pregnancy the rate of fetal anomalies was not above the background level.²⁰ In contrast, a meta-analysis of the use of glucocorticoids during pregnancy found a 3.4-fold increase in risk of cleft palate formation in offspring who were exposed to glucocorticoids during pregnancy.²¹ This risk goes away after the first trimester. Glucocorticoids can contribute to premature rupture of the membranes and babies who are small for gestational age. Pregnant women who take

glucocorticoids are at increased risk of the development of gestational diabetes, hypertension, and osteoporosis.

Glucocorticoids can be used in pregnant patients for whom NSAIDs have failed or who require immunosuppression. Patients should be informed that there is a slightly increased risk of cleft palate formation in fetuses exposed to glucocorticoids during the first trimester. Clinicians should use the lowest possible dose of glucocorticoids that controls clinical symptoms. In patients who have been treated with glucocorticoids throughout pregnancy and who have a prolonged labor or require a cesarean section, stress doses of steroids (50 to 100 mg hydrocortisone sodium succinate intravenously every 8 hours) should be administered during labor and delivery.

Five percent of the glucocorticoid dose is secreted in breast milk. This is not an issue for lactating mothers who are taking less than 20 mg/day. However, in patients who are taking more than 20 mg/day, the recommendation is to pump and discard breast milk produced during the 4 hours immediately following the steroid dose.²²

ANTIMALARIALS

In rheumatology practices, the 4-aminoquinoline antimalarial agents hydroxychloroquine and chloroquine are used for the treatment of mild inflammatory arthritis, SLE, and connective tissue disorders. In animals, use of these medications during pregnancy can cause chorioretinotoxicity in the fetus.²³ Although the FDA classifies these medications as category C for use during pregnancy, substantial evidence now exists to show that these drugs are compatible with pregnancy. In lower doses, the antimalarials have been safely used in pregnancy for malarial prophylaxis.²⁴ In higher doses, these medications have been given to pregnant patients with SLE with no increased reports of fetal malformations. Khamashta and colleagues²⁵ reported on 33 women who safely took antimalarials during pregnancy, and Parke and Rothfield²⁶ reported on 16 lupus patients who took antimalarials during pregnancy with no adverse effects. Furthermore, there is some evidence that continuing hydroxychloroquine therapy in patients with SLE during pregnancy may improve maternal and fetal outcome.²⁷ A survey of North American rheumatologists revealed that 69% of these physicians maintain patients on this medication during pregnancy, a result that supports the concept that hydroxychloroquine is compatible with pregnancy.²⁸ Current evidence and practice suggest that antimalarials are compatible with pregnancy. Patients with lupus or connective tissue disease should be encouraged to continue these medications during pregnancy to ensure better outcomes. Those with inflammatory arthritis can opt to discontinue this medication because in these patients symptoms are likely improve during pregnancy.

According to the American Academy of Pediatrics, this medication can be used in nursing mothers.¹³

GOLD

Although gold salts were among the first effective treatments for RA and inflammatory arthritis, they are now rarely used due to the development of other disease-modifying agents. In animals, gold salts cross the placenta and can cause congenital abnormalities, including hydrocephaly and hydronephrosis.²⁹ In humans, the data are limited on the use of gold during pregnancy. There is one case report of congenital anomalies occurring in an infant in which the mother was treated with gold salts.³⁰ Gold therapy should be stopped during pregnancy, although the long half-life of gold salts means that there are usually significant body stores of this medication at the time of pregnancy. This medication is considered to be compatible with breastfeeding.

SULFASALAZINE

Sulfasalazine was initially developed in the 1930s to treat RA. However, until the past two decades, this drug has been used mainly to treat inflammatory bowel disease. Sulfasalazine crosses the placenta with its metabolite sulfapyridine. The latter can displace bilirubin from albumin, but this is not thought to be clinically relevant.³¹ Although there have been case reports of fetal malformations in humans after *in utero* exposure to sulfasalazine, a large meta-analysis did not show a statistically significantly increased risk of congenital anomalies after fetal exposure.³² Because sulfasalazine inhibits the absorption of folic acid, pregnant women should take supplemental folic acid beyond the dosages typically prescribed during pregnancy.³³ This medication may be used during pregnancy and is a good option for women who have active inflammatory arthritis.

TABLE 68.1
Toxicities of antirheumatic therapies in animals and humans

Drug	Animals		Humans		
	Embryotoxic	Fetal	Maternal	Fetal	Breastfeeding
Aspirin and NSAIDs	No	Teratogenic in high doses	No	Premature closure of the ductus arteriosus	Compatible
Glucocorticoids	No	Cleft palate Aggressive behavior	PROM Hypertension Glucose intolerance Osteoporosis Osteonecrosis	SGA Adrenal hypoplasia Promotes lung maturity Cleft palate* Stillbirth*	Crosses into breast milk at low concentration, well tolerated
Antimalarials	No	Chorioretinotoxicity	No	Case reports of pigment deposition in the retina, cochleovestibular paresis, dorsal column disease, and mental retardation	Crosses into breast milk, contraindicated
Gold	No		No		Compatible
Sulfasalazine	†	Teratogenic in rats	No	Cleft palate VSD Coarctation of the aorta Macrocephaly Oligospermia	Crosses the placenta, contraindicated
Azathioprine	Yes	Skeletal abnormalities Cleft palate Decreased thymic development and hematopoiesis	†	Diminished fertility in offspring*	Contraindicated†
6-Mercaptopurine	Yes	Cleft palate	†	SGA Prematurity Intrauterine growth retardation Cleft palate	†
Cyclosporine A	Yes	Renal tubular cell damage	Renal insufficiency	Spontaneous abortions	Contraindicated
Mycophenolate mofetil	†	†	†	Case reports: Shortened digits and hypoplastic nails Auditory canal atresia Cleft lip and palate Micrognathia Hypertelorism Ocular coloboma	Contraindicated
Methotrexate	Yes	Skeletal abnormalities Cleft palate	†	Embryotoxic Skeletal abnormalities Facial abnormalities	Contraindicated
Leflunomide				Multiple congenital anomalies	Contraindicated*
Cyclophosphamide	Yes	SGA Skeletal abnormalities Cleft palate Exophthalmos Decreased fertility	Decreased fertility in males and females	SGA Limb abnormalities Coronary artery agenesis Tumors in offspring*	Contraindicated
Intravenous immunoglobulin	†	†	†	SGA Autoantibodies	†
Etanercept, adalimumab, infliximab	†	†	†	VACTERL anomalies? Placental transfer?	†
Certolizumab					
Rituximab	†	†	†	†	†

*Theoretical risk or case reports only.

†No information available.

‡Conflicting information.

NSAIDs, nonsteroidal antiinflammatory drugs; PROM, premature rupture of the membranes; SGA, small-for-gestational age offspring; VSD, ventricular septal defect.

Sulfasalazine interferes with both spermatogenesis and sperm motility. Therefore discontinuing this medication for 3 months before attempting conception is recommended.³⁴ Due to a report of bloody diarrhea in a breastfed infant whose mother was ingesting sulfasalazine, the American Academy of Pediatrics warns against use of this medication by nursing mothers; nonetheless, in certain circumstances it may be appropriate to continue this medication in lactating women.^{13,35}

IMMUNOSUPPRESSIVE AGENTS

Immunosuppressive agents are used in the treatment of rheumatic diseases to manage end-organ involvement and as steroid-sparing agents. Fortunately, we have a plethora of information on the use of these medications during pregnancy because of information gleaned from large transplant

TABLE 68.2
Rheumatic diseases during pregnancy

Disease	Activity during pregnancy
Rheumatoid arthritis	Remits in 50%-70% of cases
Systemic lupus erythematosus	Stable or worsens; active renal disease is particularly problematic
Psoriatic arthritis	Generally improves
Scleroderma	Limited data
Dermatomyositis	Limited data

registries. Azathioprine and its active metabolite 6-mercaptopurine, cyclosporine, and mycophenolate mofetil are the major immunosuppressive agents used in the treatment of rheumatic diseases. Their safety for use in pregnancy is discussed in the following sections.

Azathioprine and 6-mercaptopurine

The purine analogues azathioprine and its major metabolite 6-mercaptopurine have been used for the treatment of SLE, RA, and the spondylitic variants. In pregnant rats treated with high doses of azathioprine (20 mg/kg/day), trophoblastic damage was observed.³⁶ In humans, the placenta is unable to metabolize azathioprine into its metabolite 6-mercaptopurine, which suggests that little if any of the biologically active form of this medication reaches the fetus.³⁷ Although there have been case reports of infants born with pancytopenia, combined immunodeficiency, chromosomal abnormalities, and craniofacial malformations after *in utero* exposure to azathioprine,^{38,39} several large case series have failed to demonstrate an increased risk of congenital anomalies in exposed fetuses. In 142 transplant recipients who were given azathioprine during pregnancy, reported anomalies in infants included metatarsus adductus, kidney malformation, ventricular septal defect, patent ductus arteriosus, and a hearing deficit. Nonetheless, the number of observed anomalies was not above the background rate.⁴⁰ Moreover, patients were concomitantly receiving other medications such as glucocorticoids and cyclosporine, so attributing risk to any particular medication is difficult. Lower birth weights have been described in infants whose mothers took azathioprine during pregnancy; however, whether this is due to premature delivery or true small size for gestational age is a subject of debate.^{41,42} The rate of premature delivery is likewise difficult to interpret given that patient and physician preference for delivery time is often not discussed in these studies.

The FDA classifies this medication as risk category D for safety in use during pregnancy. Despite this classification, the existing data suggest that azathioprine does not increase the risk of congenital anomalies above background rates. This medication is considered a viable option for immunosuppression during pregnancy.

In animals, 6-mercaptopurine is teratogenic, inducing cleft palate formation, microcephaly, and dilatation of the cerebral ventricles.^{43,44} In humans, there are few case series available for review. In one case series of 155 patients with inflammatory bowel disease who took 6-mercaptopurine during pregnancy, no increase was seen in rate of conception failures or major congenital malformation.⁴⁵ Another reassuring study demonstrated no increase in congenital anomalies in 215 pregnancies in patients with inflammatory bowel disease treated with thiopurines.⁴⁶ The question of when to discontinue this medication in male patients who wish to father a child is important. In one series of 13 male patients who had taken this medication in the 3 months preceding conception, there were two spontaneous abortions among their wives and two offspring born with skeletal congenital anomalies.⁴⁷ Therefore this medication should be discontinued in men 3 months before a planned conception.

Both azathioprine and 6-mercaptopurine can cause immunosuppression in the newborn and should not be used by nursing mothers.

Cyclosporine

In rodents, cyclosporine crosses the placenta in very low concentrations.⁴⁸ Pregnant rodents administered high doses of cyclosporine (25 mg/kg/day) have increased fetal mortality and renal abnormalities, although other studies have not shown any impact on organogenesis.^{49,50} There are differing

opinions as to whether or not cyclosporine crosses the placenta in significant concentrations in humans.^{51,52} Regardless, there seems to be no increased risk of teratogenicity over background rates with *in utero* cyclosporine exposure. In one study of 154 pregnancies in renal transplant patients in which the mothers were taking cyclosporine, there was no increase in the incidence of malformations; however, the babies exposed to cyclosporine were smaller and more often premature, and the mothers had an increased incidence of maternal diabetes and hypertension.⁵³ In the U.S. National Transplantation Pregnancy Registry, 500 pregnancies have been reported in which the fetuses were exposed to cyclosporine. There was no increase in congenital anomalies, although the live birth rate was lower in those pregnant patients who received cyclosporine. Importantly, sicker patients tend to be taking cyclosporine, which may help explain this observation.⁵⁴ Finally, a recent meta-analysis concluded that cyclosporine does not appear to be a major teratogen, although it may be associated with increased rates of prematurity.⁵⁵

There is some concern that *in utero* exposure to cyclosporine may impair the development of T, B, and natural killer cells. Whether this will have long-term impact and whether immunization schedules in these infants should be modified is unclear.⁵⁶ The literature suggests that cyclosporine may be used for immunosuppression during pregnancy. This medication is not compatible with nursing because of the risk of immunosuppression in the offspring.

Mycophenolate mofetil

Mycophenolate mofetil is a purine synthesis inhibitor that has been used to prevent organ rejection. More recently, it has been used in the treatment of lupus nephritis.⁵⁷ In animals, this agent may cause premature meiotic maturation.⁵⁸ In a case series of 57 pregnancies in women taking mycophenolate mofetil a lower than expected rate of live births and a higher than expected rate of congenital anomalies (6 per 29 live births) was reported.⁵⁹ This medication is classified as a category C drug by the FDA. Given the high rate of reported anomalies, this medication should be avoided during pregnancy and nursing.

Methotrexate

Methotrexate is a folate antagonist that has been used widely over the past 2 decades for the treatment of RA and other inflammatory conditions. Current practice suggests that this medication should be the mainstay of therapy of RA.⁶⁰ In pregnant rodents, this agent causes skeletal abnormalities in the offspring and increased fetal resorption rate.^{61,62} In humans this medication is profoundly abortifacient and is commonly used for the non-surgical treatment of ectopic pregnancies.⁶³ It can also cause severe teratogenicity including craniofacial abnormalities and mental retardation.⁶⁴ Most of the toxicity appears to occur during the sixth through eighth weeks of gestation and at dosages higher than 10 mg/wk. There have been a few case reports of offspring in whom there was no teratogenicity when exposed to this medication before 6 weeks of gestation and at dosages lower than 10 mg/wk.^{65,66} Nonetheless, a recent review of this topic by Lloyd and colleagues⁶⁷ suggests that there is no safe window. In their series encompassing 42 pregnancies there were 10 fetal abnormalities after *in utero* exposure to methotrexate in the first trimester. They suggest that the washout period before conception in both men and women should be 6 months. Donnemfeld and associates⁶⁸ suggest that the medication should be discontinued 12 weeks before conception because of the high spontaneous abortion rate. The FDA has classified methotrexate as a category X risk for use during pregnancy. Thus it is imperative to counsel sexually active patients who have the potential to conceive about consistently using reliable birth control. The American College of Rheumatology recommends that men discontinue this medication 3 months before attempting conception. They suggest that women wait at least one ovulatory cycle after stopping methotrexate before trying to become pregnant. This medication is not compatible with breastfeeding.

Given the widespread use of methotrexate in rheumatic disorders, inadvertent *in utero* exposure can and does occur.^{65,66} Thus clinicians may be faced with how best to counsel patients regarding whether to proceed with a pregnancy or not. Reproductive choices are intensely personal and are based on cultural, religious, and individual belief systems. The role of the clinician is to provide as much information as possible on reported fetal outcomes after medication exposures so that patients can evaluate the potential risk to the fetus. In addition to providing this information, referring the patient for high-resolution fetal ultrasonography that can evaluate organ development can help the patient make an informed decision about how to proceed with the pregnancy.

LEFLUNOMIDE

Leflunomide is used to treat inflammatory arthritis, Behçet syndrome, and other disorders. This medication is extremely teratogenic (risk category X) and is contraindicated in pregnancy.

Recently there was a report on 45 pregnancies in which inadvertent exposure to leflunomide occurred either just before conception or during gestation. The authors reported that 2 of 16 offspring exposed to leflunomide *in utero* had major malformations and an additional three had minor anomalies.⁶⁹ Although the authors conclude that leflunomide is not a major teratogen, the numbers suggest a higher than background rate of congenital anomalies. Thus patients who are taking leflunomide should be carefully counseled regarding appropriate contraception. Because of its extremely long half-life, drug elimination with cholestyramine is recommended for women who wish to become pregnant. The manufacturer recommends that cholestyramine be given at a dosage of 8 g three times a day for 11 days and that drug levels then be measured. Without cholestyramine, it can take up to 2 years to eliminate this drug.

CYCLOPHOSPHAMIDE

Cyclophosphamide is a cytotoxic agent that is the backbone of many cancer chemotherapy regimens. In people with SLE and vasculitis, this medication has greatly reduced the morbidity and mortality of renal disease and other organ involvement.⁷⁰ In pregnant mice, cyclophosphamide causes chromosomal rearrangements and impairs blastocyst development in embryos.⁷¹ In humans, cyclophosphamide exposure during pregnancy can lead to problems with digit development and limb formation, iris development, and coronary artery abnormalities.^{72,73} Although there have been case reports of individuals being treated for granulomatosis with polyangiitis (at 17 weeks of gestation and beyond) and Hodgkin lymphoma (in third trimester) with no adverse outcomes, cyclophosphamide should be avoided during pregnancy.^{74,75} Patients who need to be treated with this medication during the first trimester and early second trimester of pregnancy should be counseled about the high risk of congenital anomalies in the fetus. Cyclophosphamide is transferred into breast milk and should not be used by nursing mothers.

Prolonged use of cyclophosphamide can also induce infertility in women. Risk factors for cyclophosphamide-induced infertility include age older than 30, more than 15 pulses of therapy, and a cumulative dose of more than 10 g. Concomitant use of leuprolide acetate or oral contraceptives may offset this effect.⁷⁶

INTRAVENOUS IMMUNOGLOBULIN

Intravenous immunoglobulin (IVIG) is used for the treatment of dermatomyositis and other rheumatic conditions. Data on the use of this medication during pregnancy are limited. There have been several case reports about the safety of this medication during pregnancy. Moreover, this medication has also been used to manage the obstetric complications of antiphospholipid syndrome without inducing congenital malformations.⁷⁷ This medication is considered compatible with pregnancy.

TUMOR NECROSIS FACTOR- α BLOCKADE AND INHIBITORS

Biologics that are directed against the tumor necrosis factor- α (TNF- α) receptor or inhibit this cytokine are successful in treating RA.⁷ These medications are rated category B for use during pregnancy. Although there have been two reports to the FDA of potential congenital anomalies consistent with VACTERL syndrome,⁷⁸ the significance of this finding has been questioned.⁷⁹ A recent case series of 118 pregnancies in which there was exposure to anti-TNF- α agents either before conception or during pregnancy demonstrated a higher rate of spontaneous miscarriage (several of the patients were taking methotrexate and leflunomide as well) but no increased incidence of congenital anomalies.⁸⁰ Nonetheless, in most circumstances it is recommended that these medications be discontinued before pregnancy or at the time of a confirmed pregnancy test result. In cases of severe disease in which patients have previously not tolerated discontinuation of their TNF- α blockers, one can consider continuing these medications during pregnancy.

Animal data suggest that an anti-TNF- α pegylated Fab monoclonal antibody may not cross the placenta in significant concentration to accumulate in the fetus.⁸¹ More recent human data for 152 pregnancies in women exposed to certolizumab pegol, a pegylated anti-TNF- α agent, suggest no increased rate of congenital abnormalities or pregnancy complications when this medication is used during pregnancy.⁸²

RITUXIMAB AND OTHER EXPERIMENTAL THERAPY

Data on the safety of rituximab, abatacept, and other depleting therapies during pregnancy are limited. A recent review of data for 153 pregnancies involving fetal exposure to rituximab revealed 11 hematologic abnormalities, 4 neonatal infections and 2 congenital malformations in 90 live births.⁸³ The authors concluded that rituximab should be avoided for 12 months before conception. Given that immunoglobulins do not cross the placenta until after the first trimester, this may be overly conservative. Nonetheless, whether this medication can safely be used closer to pregnancy is unknown. Data on anakinra, abatacept, tocilizumab, and belimumab are limited, so no conclusions can be drawn. Current recommendations are to avoid these medications during pregnancy.

CONCLUSION

Managing the pregnant patient with an underlying rheumatologic disorder is challenging. Ensuring that the patient's disorder is in remission or under good control with medications compatible with pregnancy before conception is crucial for good maternal and fetal outcomes. The potential toxicities of medications to both the mother and the fetus must be weighed against the need for disease control in situations of disease flare. Often there is no ideal therapy for a given situation. One approach (Table 68.3) is to treat mild symptoms with NSAIDs (up until the third trimester) and/or low doses of glucocorticoids. If inflammatory arthritis is the major complaint, sulfasalazine and possibly TNF- α blockers can be used if disease is flaring during pregnancy. For some patients with extremely active arthritis, it may be difficult to withdraw medications before conception. In these patients, changing to medications compatible with pregnancy such as sulfasalazine and TNF- α blockers that may not cross the placenta may be the best approach. Patients with SLE should continue to take their antimalarials during pregnancy. For moderate disease, higher doses of glucocorticoids, azathioprine, and cyclosporine can be used. For severe diseases, pulse steroid therapy, IVIG, azathioprine, and cyclosporine can be used. Cytotoxic agents should be reserved for life-threatening situations. Limited data on biologics preclude their use during pregnancy in most circumstances. In all cases, the treating clinician and the patient should discuss the potential hazard to the mother and/or the fetus of any therapy.

TABLE 68.3

Treatment recommendations*

Symptom/condition	Treatment options
Mild arthralgias, arthritis, pleuritis, skin rashes	Nonsteroidal antiinflammatory drugs (first two trimesters only) Low-dose glucocorticoids (5-10 mg prednisone a day)
Inflammatory arthritis	Consider sulfasalazine in addition to above
Systemic lupus erythematosus or connective tissue disease	Consider antimalarials
Moderate disease	Glucocorticoids (higher doses), azathioprine, 6-mercaptopurine, cyclosporine
Severe disease	Pulse steroids, intravenous immunoglobulin, azathioprine, cyclosporine
Life-threatening disease	Cyclophosphamide

*Methotrexate and leflunomide should be avoided.

Aspiration and injection of joints and periarticular tissue and intralesional therapy

■ ESPERANZA NAREDO ■ MARINA RULL

- Synovial aspiration is a basic bedside diagnostic tool in rheumatology.
- Major diagnostic errors can be made by simply assuming the nature of an effusion.
- Corticosteroid injection and infiltration and viscosupplementation are basic treatment tools in rheumatology, orthopedics, physiatry, and general medicine. These procedures pose minimal risk to patients when performed properly.
- Synoviorthesis, or medical synovectomy, may be achieved by the intraarticular injection of sclerosing agents or radioactive material but requires specialized knowledge.
- Rheumatologists trained in musculoskeletal ultrasonography are able to perform, at low cost and minimal risk to patients, procedures that in the past required expensive and even risky techniques.
- Ultrasound is a valuable bedside tool for guiding accurate and safe musculoskeletal fluid aspiration and perilesional or intralesional injections. Ultrasound provides confirmation of the clinical diagnosis and the indication for injection. Real-time ultrasound enables us to place the needle correctly, deliver medication accurately, and visualize the drug during and after the procedure.

INDICATIONS FOR ASPIRATING OR INJECTING MUSCULOSKELETAL TISSUES

Aspiration of fluid for diagnostic or therapeutic purposes

Joint aspiration has a number of major indications. In patients in whom infection, crystal, or blood is the suspected cause of monoarthritis or a bursal or tendon sheath lesion, aspiration and synovial fluid analysis are essential and obligated for diagnosis.¹⁻³ In patients with tense joint effusions, aspiration of synovial fluid provides prompt relief of pain and permits the patient to move or bear weight on the affected joint. Finally, in hemarthrosis or septic arthritis, the blood and pus within a synovial cavity may be damaging to the joint cartilage and synovial membrane, so evacuation of the fluid is necessary to avoid permanent joint damage. Large articular effusions should be drained as fully as possible to decrease pressure, improve synovial circulation, and prevent muscle atrophy. Synovial fluid analysis is discussed in Chapter 31.

Key practice issues

Procedure

Aspiration or injection of joints or soft tissues is an outpatient procedure that does not require equipment (Table 69.1) unless performed under ultrasound (US) guidance. The procedure must be explained fully to the patient. Universal precautions focused on sterilization must be followed during the procedure.

Blind aspiration

The patient should be in a supine position for lower extremity procedures and in a sitting position in a chair with armrests for upper extremity

procedures. Anatomic landmarks need to be identified by palpation and the needle site marked. The skin must then be cleaned carefully with antiseptic agents. For local anesthesia, the skin and subcutaneous tissue are infiltrated with 1% or 2% lidocaine without epinephrine (adrenaline) via a small-bore needle down to the level of the periarticular lesion or joint capsule. However, experienced physicians may use topical ethyl chloride or no anesthetic at all. With proper technique the needle passes freely through the extraarticular tissues and a “pop” may be felt as the needle enters the joint. The ease with which fluid can be withdrawn depends on the size of needle used, the viscosity of the fluid, and the presence of any fibrin clots or “rice bodies” in the joint fluid. Free flow of fluid is often suddenly interrupted because of clogging of the end of the needle by the synovial membrane or debris. Rotating the needle, withdrawing it slightly, or even reinjecting a little of the fluid will often help unclog the needle. If corticosteroids or other substances are to be injected, this should be done through the same needle without removing it from the joint.

Ultrasound-guided aspiration and injection

US can be a valuable bedside tool for guiding musculoskeletal fluid aspiration and perilesional or intralesional injections accurately and safely.^{4,5} US provides confirmation of the clinical diagnosis and the indication for injection. The characteristics of joint effusions (e.g., extension, solid or fluid content, internal synovial hypertrophy) that should be aspirated are visualized with US. This information is very useful for planning the best access to the fluid while avoiding synovial hypertrophy or solid material inside the fluid and for selecting the appropriate needle for the procedure. Real-time US enables correct placement of the needle and accurate delivery of any medication by visualizing the drug suspension during and after the procedure. Injections into anatomic structures adjacent to the intended target (e.g., vessels, nerves, subcutaneous fat) can be avoided because they are easily identified with US. The learning time for US-guided injections is usually short.

Several studies have demonstrated greater accuracy with US-guided joint aspiration and soft tissue injection than with blind injection.⁶ Although the impact of accurate needle placement on the therapeutic response to local corticosteroid injection needs further elucidation,⁷ it seems clear that US guidance, if available, can maximize accuracy of the injection into the intended target and minimize adverse effects related to the procedure.

The capability of US to guide injections is based on the easily detectable hyperechoic appearance of foreign bodies such as needles and other puncture devices. The needle is visualized as a bright hyperechogenic line, often with a posterior reverberation artifact, when it is directed parallel to the long axis of the contact surface of the transducer (i.e., probe) and perpendicular to the US beam. Needle imaging is possible with many superficial injections. When the transducer is placed transverse to the route of the needle, only the tip of the needle is detected as a bright hyperechogenic focus as it reaches the target under the probe. The echogenicity of the needle decreases when its direction is oblique to the US beam. The size of the needle does not significantly influence its visualization.

US-guided injections should be carried out by following five steps:

1. US assessment of the clinically pathologic area and confirmation of the clinical diagnosis and indication for injection
2. Planning of the injection route and needle characteristics
3. Sterilization of the patient's skin and probe
4. Skin puncture under US guidance

5. Confirmation of correct fluid aspiration or drug location (or both) with US before removing the needle

Two methods of guiding musculoskeletal needle placement with US are used:

1. Skin marking or indirect method (Fig. 69.1a and b). With this method, US is used to select the potentially most successful puncture site over the target but not to guide progression of the needle. After scanning the pathologic area, the target is imaged in two perpendicular planes. When the target is in the center of the screen in both the longitudinal and transverse planes, the edges of the probe are drawn on the skin with a skin-marking indelible pen. The depth of the target is measured perpendicular to the skin. The probe is then removed and a mark is drawn on the skin in the center of the previously drawn rectangle. After sterilization of the skin, the needle is inserted into the mark and directed to the target.
2. Needle guidance under direct US control (Fig. 69.2a and b). The patient's skin and the transducer are sterilized. Sterile gel is applied to the skin if the entry point chosen is close to the transducer. Some ultrasonographers use a sterile sleeve for the transducer (adequate transducer contact is provided by placing acoustic gel within the

sleeve). Continuous monitoring of progression of the needle under direct US visualization, although more experience and hand-eye coordination are required, provides more accurate control of progression of the needle from the skin to the target during the procedure. Aspiration of fluid (see Fig. 69.2c to e) and injection of medication can be seen in real time. Most ultrasonographers carry out direct US-guided injections via a freehand technique. A needle guide can also be installed on the transducer to hold and direct the needle for injecting deep lesions. However, these devices make the procedure more time-consuming and expensive and the approach less flexible.

At the end of any procedure, the needle should be withdrawn swiftly and light pressure placed on the needle site in the skin. Application of simple adhesive plaster (tape) for a few hours is all that is usually required thereafter.

Aftercare

In most cases it is sensible for patients to rest the affected joint for 24 to 48 hours after a therapeutic injection to minimize leakage of the therapeutic agent following lower extremity procedures and improve the antiinflammatory response.

TABLE 69.1

Equipment required for joint and soft tissue injections

Procedure	Details
Skin preparation	Antiseptic solution (povidone-iodine), alcohol swabs, 4 × 4 gauze pads
Local anesthetic	1% or 2% lidocaine without epinephrine
Needles	No. 23-27 for local anesthetic, 18 gauge for large to moderate-sized joints (knees, shoulders, ankles, etc.), No. 23-27 for small joints (wrists, metacarpophalangeal joints, etc.)
Syringes	3 or 5 mL for anesthetic-steroid injection and 10-50 mL for joint aspiration (sterile steroid–prefilled syringes are preferable when available)
Miscellaneous	Gloves, forceps for removing needles from the syringe, specimen tubes/plates for culture and fluid studies

All the supplies required should be assembled in advance. Importantly, the needle must be long enough to reach the intended place and have a caliber adequate for the nature of the fluid. Although standard needle lengths work well in thin patients, longer needles and even a spinal needle may be required in obese patients. On the other hand, a 1-mL syringe with a half-inch No. 27 needle is particularly useful for infiltrating superficial structures such as the interphalangeal, metacarpophalangeal, and metatarsophalangeal joints; the digital flexor tendon sheaths; the carpal tunnel; de Quervain tenosynovitis; and the elbow joint through the lateral approach. Purulent effusions require No. 18 or 16 needles. Failure to fully drain a septic joint indicates large debris or loculation and calls for tidal lavage, arthroscopy, or arthrotomy. All material should be new and sealed when used; do not use the rest of opened vials.

CONTRAINDICATIONS

There are few absolute contraindications to joint or soft tissue aspiration and injection; if infection is suspected, fluid should always be aspirated from a joint. For other indications, the procedure should probably be avoided if the overlying skin or subcutaneous tissue is infected or if bacteremia is suspected. The presence of a significant bleeding disorder or diathesis or severe thrombocytopenia may also preclude joint aspiration. However, if it is deemed necessary for diagnosis or therapy, the procedure may be carried out after appropriate coverage for the bleeding disorder. Warfarin anticoagulation with international normalized ratios in the therapeutic range is not a contraindication to joint or soft tissue aspiration or injection.⁸ Aspiration of a joint with a prosthesis is often best left to surgeons.

CORTICOSTEROID INJECTIONS

Corticosteroid injections are frequently used to achieve a local antiinflammatory response. Indications for their use include the presence of persistent inflammation at a single site. Synovial joints and other cavities (e.g., bursae, cysts) should generally be injected with a long-acting crystalline form of corticosteroid such as triamcinolone hexacetonide or methylprednisolone acetate. These crystals persist longer in the fluid than do mixtures of depot and soluble betamethasone⁹ and thereby allow continued local release into the targeted area. Only a relatively small proportion escapes into the general circulation, but during the first 24 hours after injection, patients may experience flushing or other evidence of a corticosteroid “pulse.” For periarticular injections, particularly subcutaneous bursae and de Quervain tenosynovitis,

Fig. 69.1 (a) Ultrasound-guided indirect method of injection into the right tibiotalar joint. An extended paper clip is displaced between the probe and the skin until its tip is imaged at the center of the target. The puncture point is marked in the patient's skin with the clip. (b) The needle is inserted perpendicular to the skin.

Fig. 69.2 (a) Ultrasound-guided direct method of injection of the right hip joint. The needle is inserted adjacent to the transducer and directed to the anterior recess of the hip. (b) On the ultrasound image the tip of the needle (arrowhead) has a hyperechogenic appearance inside the hip effusion. The needle (arrow) appears hyperacute in the iliopsoas muscle. fh, femoral head; fn, femoral neck. (c) Ultrasound-guided injection of subdeltoid bursitis. (d and e) Successful fluid aspiration can be visualized in real time. Arrowheads indicate needle tips. bt, biceps tendon; bg, bicipital groove; SDB, subdeltoid bursa.

methylprednisolone acetate should be used because the less soluble (and therefore more potent) triamcinolone hexacetonide is likely to induce skin atrophy.

Corticosteroid doses vary with the structure injected. For each of the procedures discussed, a dose range based on the use of methylprednisolone acetate is shown in each section. If the more potent triamcinolone hexacetonide is used, the lower dose of the indicated range should be chosen. Intracavitary position of the needle can be ascertained by withdrawing some joint fluid or checking to see whether the cavity distends as fluid is injected. In soft tissues, correct positioning may be ascertained by elimination of pain with a preceding lidocaine infiltration. However, if available and in procedures in which needle misplacement is common, US guidance gives the best results.¹⁰ Resting the injected site for 24 to 48 hours following the procedure is generally recommended.

The most common indications for aspiration and injection of the musculoskeletal system are presented in this chapter.

Complications of corticosteroid injections¹¹

- **Local bleeding.** In patients without a bleeding diathesis, pressing the puncture site with sterile gauze for about a minute—or longer in those taking prophylactic aspirin—stops the bleeding. In procedures on the upper extremity, arm elevation prevents venous bleeding.
- **Facial flushing.** Flushing occurs in perhaps 40% of cases. Transient and inconsequential, it may nevertheless worry unwarned patients.
- **Postinjection flare.** Corticosteroid crystal-induced synovitis occurs in approximately 5% of intraarticular injections. Pain appears several hours following the procedure and may last from a few hours to 1 day. Persistent pain and mounting swelling may indicate infection; these joints should be reaspirated for Gram stain and aerobic and anaerobic culture.
- **Skin atrophy.** This complication occurs frequently, particularly in elderly individuals and with superficial infiltrations. The condition is characterized by cigarette paper-like skin, recurrent ecchymosis, and chronic pressure pain.
- **Fat atrophy.** This complication may occur with repeated fatty tissue infiltration, such as for Morton neuroma and proximal plantar enthesopathy.
- **Skin hypopigmentation.** Superficial corticosteroid infiltrations such as for de Quervain tenosynovitis often result in a hypopigmented patch, which may be quite disfiguring in people with dark skin.
- **Embolia cutis, livedoid dermatitis, or Nicolau syndrome.** A rare adverse reaction to drug injections, including corticosteroids, this complication is characterized by microembolic obstruction of a dermal artery, which causes a livedoid lesion and necrotic ulcers. Pain is felt around the injection site, followed by a livedoid and hemorrhagic patch, and finally necrosis of the skin, subcutaneous fat, and muscle occurs.
- **Infection.** The reported rate of septic arthritis following corticosteroid injection has been on the order of five cases per 100,000 procedures

when the corticosteroid is aspirated from a vial and less than one case per 100,000 procedures when prefilled syringes are used.¹² Patients who have severe immunodeficiency problems, as well as those with implants, may be at greater risk. It is important to not reuse leftovers of open vials because of staphylococcal contamination.

- Tendon rupture. A ruptured tendon following a corticosteroid injection may indicate abuse of the procedure, intratendinous injection, or coincidental rupture caused by the very condition that led to the injection. Conditions that result in spontaneous tendon rupture include dorsal wrist tenosynovitis and posterior tibialis tenosynovitis in patients with rheumatoid arthritis (RA); degenerative changes in the supraspinatus, long biceps, or Achilles tendon; chronic corticosteroid use; fluoroquinolone-induced Achilles tendinopathy; uremia; hyperparathyroidism; and systemic lupus erythematosus.
- Corticosteroid arthropathy. Abuse of intraarticular injections may result in a Charcot-like arthropathy similar to that described with calcium pyrophosphate crystal deposition disease (see Chapter 190).
- Nerve damage. With knowledge of regional anatomy, this complication should largely be avoided. However, because anatomic variations are frequent, insertion of the needle should always be done cautiously.
- Osteonecrosis. This is a reported complication of articular or soft tissue corticosteroid infiltration abuse.
- Systemic complications. Corticosteroid injections cause pituitary inhibition, which recovers in 1 to 2 weeks,¹³ and in diabetics, transient hyperglycemia lasting 2 to 3 days; anaphylactic shock, albeit exceedingly rare, may also occur.¹⁴

OTHER THERAPEUTIC INJECTIONS

Viscosupplementation

Viscosupplementation is the term that describes the use of intraarticular hyaluronates for the treatment of pain in osteoarthritic joints. Two types of agents are in use. One is hylan G-F 20, a high-molecular-weight preparation (molecular weight of 6,000,000). The other type includes lower-molecular-weight hyaluronan preparations in the range of 800,000 to 2,000,000. Viscosupplementation is often effective in relieving pain in patients with osteoarthritis (OA).^{15,16} When compared with intraarticular corticosteroids, the beneficial effect of viscosupplementation is that it has delayed action but lasts longer.¹⁷ The relative merits of hylan G-F 20 and the lower-molecular-weight compounds are still in dispute.^{18,19} Although these agents were initially used for the knee, other joints such as the trapeziometacarpal joint, the shoulder, the hip, and the ankle have all been treated with benefit. Viscosupplementation is associated with several risks. Postinjection pain, not necessarily associated with a significant effusion, has been common in the authors' experience. Another complication is a pseudo-septic effusion associated with pyrexia.²⁰ These reactions require hospital admission and intravenous antibiotics pending the results of culture. A granulomatous reaction has also been reported.²¹ A further risk with viscosupplementation is an allergic reaction in patients with avian protein allergy (e.g., products, feathers). The usual indications for viscosupplementation include (1) patients who cannot tolerate antiinflammatory medications and whose pain is unrelieved with analgesics and (2) those with advanced OA who refuse or are not suitable candidates for surgery. The medication and administration costs of viscosupplementation are considerable. However, a Canadian cost analysis has shown superiority of viscosupplementation over appropriate care without viscosupplementation.²²

Synoviorthesis

Synoviorthesis, or medical synovectomy, may be achieved with the intraarticular injection of chemicals such as osmic acid, rifampicin, and rifamycin or radioactive colloids such as yttrium-90 (⁹⁰Y), erbium-169 (¹⁶⁹Er), dysprosium-165 (¹⁶⁵Dy), and gold-198 (¹⁹⁸Au), among others. The procedure may be used in patients with RA, OA, pigmented villonodular synovitis,²³ and other chronic effusive conditions, as well as in those with hemophilia to terminate recurrent hemarthrosis.²⁴ Chemical agents are believed to be less efficacious than radioactive colloids, and among these, beta-emitting radioisotopes such as ⁹⁰Y, ¹⁶⁹Er, and ¹⁶⁵Dy are preferred over gamma-emitting radioisotopes such as ¹⁹⁸Au, which cause total body irradiation. Few randomized controlled trials of radioactive and chemical synoviorthesis have been conducted.²⁵ Adverse effects of radioactive synoviorthesis are uncommon. A possible untoward local effect is a burning sensation in the needle track. This may be prevented by injecting a corticosteroid suspension while slowly removing the injecting needle. A greater concern has been

a possible oncogenic effect of the radioactive colloid. However, although chromosomal damage has been found rather frequently in peripheral blood following these procedures, a 30-year Finnish follow-up study of ⁹⁰Y synoviorthesis in more than a thousand patients failed to show excess cancer deaths.²⁶ Thus, radioactive synoviorthesis, a low-risk, relatively low-cost outpatient procedure that minimally disrupts the patient's activities, is a plausible alternative to surgical synovectomy in carefully selected patients. In hemophilia, according to experts, failure of three consecutive radioactive synoviorthesis procedures is an indication for open or arthroscopic synovectomy.

Other injections

Other medications that can be injected into the musculoskeletal system with controversial efficacy are sclerosants and platelet-rich plasma to ameliorate pain and improve healing of tendinoligamentous structures and botulinum toxin for the relief of muscle pain.

The next section of this chapter focuses on the most frequent procedures involving corticosteroid injection from an anatomic perspective.

WRIST AND HAND

Finger and metacarpophalangeal joints

Indications. Active Bouchard nodes, RA,²⁷ psoriatic arthritis. US guidance is not required.

Corticosteroid dose. 10 to 15 mg methylprednisolone acetate (No. 25 or 27 needle).

Approach. Dorsolateral with the digit in semiflexion (Fig. 69.3, Figs. e69.1 and e69.2). Note that in this and other clinical pictures the skin had been sterilized with alcohol and the needle seen in place was for injection of local anesthetic before injection of the steroid. Multiple joints may be injected during the same session.

Precautions. Do not overdilate the joint or joints. Fluid tends to back up; apply firm pressure with sterile gauze for at least 2 minutes following the procedure.

Complications. Joint hyperlaxity, capsular calcification (frequent but inconsequential).

First carpometacarpal joint

Indications. Painful OA. The efficacy of steroid injection has been disputed.²⁸ Viscosupplementation may be useful as an alternative to surgery.²⁹ US guidance is not required.

Corticosteroid dose. 15 to 30 mg methylprednisolone acetate (No. 25 or 27 needle).

Approach. A common entry site is at the anatomic snuffbox while flexing the thumb across the palm, which optimally exposes the joint just proximal to the protruding base of the first metacarpal (Fig. 69.4). A palmar approach is generally used to inject this joint under US guidance.

Precautions. Avoid the radial artery as it traverses the anatomic snuffbox.

Complications. None.

Fig. 69.3 Injection of the right fourth proximal interphalangeal joint in a patient with osteoarthritis.

Fig. e69.1 Injection of third metacarpophalangeal joint in a patient with rheumatoid arthritis.

Fig. e69.2 Injection of interphalangeal joint of the thumb adjacent to a Heberden node.

Wrist (radiocarpal and midcarpal joints)

Indications. For diagnosis of acute arthritis. Most cases of acute wrist arthritis are due to calcium pyrophosphate dihydrate pseudogout, gout, and septic arthritis. For injection in patients with RA, other sterile synovitis, and OA, US guidance is preferred. US allows identification of which wrist joint (e.g., radiocarpal, midcarpal) is more inflamed or has more fluid, which is important in determining the injection target.

Corticosteroid dose. 30 to 40 mg methylprednisolone acetate (No. 25 or 27 needle). Aspiration should be attempted before injection. For aspiration alone, use a No. 20 or 18 needle.

Approach with blind injections. The radiocarpal joint is approached dorsally just distal to the Lister tubercle (a bony prominence in the dorsal distal end of the radius) or at the midcarpal joint 1 cm ulnar and 5 mm distal to the Lister tubercle (Figs. e69.3 and e69.4). The wrist should be slightly palmar-flexed to assist in the procedure.

Precautions. No neurovascular structures of concern are located at this site.

Complications. None.

Trigger finger and trigger thumb

Indications. Only 30% of trigger fingers resolve spontaneously, and injections are highly efficacious.³⁰ A lower success rate of injections is seen in diabetics. US guidance is not required.

Approach. Just distal to proximal palmar crease (index) (Fig. 69.5), between the proximal and distal creases in the long finger (Fig. e69.5), and just distal to the distal crease in the ring and little fingers (Fig. e69.6) with the needle held at a 45-degree distal inclination; just proximal to the digital crease and aimed at sesamoids of the thumb (Fig. 69.6).

Corticosteroid dose. 15 to 20 mg methylprednisolone acetate mixed with 1 to 2 mL lidocaine (No. 25 or 27 needle).

Fig. 69.4 Injection of the left trapeziometacarpal joint in a patient with osteoarthritis.

Fig. 69.5 Injection of a right index trigger finger.

Precautions. Avoid intratendinous injection. Intratheath injection is not a requirement for success.³¹ Up to three injections given 3 weeks apart are allowed.

Complications. Focal palmar fat atrophy.

Digital flexor tenosynovitis

Indications. RA, psoriatic arthritis, and other inflammatory conditions.

Because the injection must be intratheath for flexor tenosynovitis, US guidance is preferred (Fig. 69.7, Fig. e69.7).

Corticosteroid dose. 15 to 20 mg methylprednisolone acetate mixed with 1 to 2 mL lidocaine (No. 25 or 27 needle).

Approach. If US is unavailable, inject as for trigger finger.

Precautions. Avoid intratendinous injection.

Complications. As with trigger finger, tendon rupture occurs occasionally.

Carpal tunnel syndrome³²

Indications. Injection is indicated for all causes of carpal tunnel syndrome except acute cases (hypoesthesia, severe pain, and tense bulging) caused by synovitis, fracture, hemorrhage, infection, and carpal tunnel syndrome in late pregnancy. US guidance is optional for routine cases but is a must for unilateral cases to rule out a mass lesion.³³

Corticosteroid dose. 30 to 40 mg methylprednisolone acetate, straight or mixed with 2 to 3 mL lidocaine (No. 25 or 27 needle).

Approach. About 10 mm proximal to the distal wrist crease and just medial to the palmaris longus tendon (Fig. 69.8, Fig. e69.8). If the palmaris longus is absent (14% of people), use a midline approach. The needle is inserted to a depth of 0.8 to 1 cm at a 45-degree distal inclination and a 45-degree lateral inclination. The corticosteroid is injected into the proximal extension of the ulnar bursa.

Precautions. Paresthesias indicate median nerve engagement; reposition the needle. Reciprocal needle motion with gentle finger motion indicates tendon engagement; reposition the needle. A wrist splint in neutral is a useful adjunct to the injection.

Complications. Pain, which may last 1 to 3 days, and a transient increase in paresthesias. The patient should be instructed to use an ice pack intermittently, 5 minutes on and 5 off, at the first hint of pain.

Fig. 69.6 Injection of a right trigger thumb.

Fig. e69.3 Aspiration of the radiocarpal joint for gout, radial view.

Fig. e69.4 Aspiration of the radiocarpal joint for gout, dorsal view.

Fig. e69.5 Injection of a right middle trigger finger.

Fig. e69.6 Injection of a right ring trigger finger.

Fig. e69.7 Ultrasound-guided direct injection for flexor tenosynovitis of the hand.

Fig. e69.8 The tendons used as landmarks for injection into the carpal tunnel are seen clearly in this patient. To the left of the needle, past the vein, two tendons are seen: the palmaris longus and, radial to this, the flexor carpi radialis.

de Quervain tenosynovitis³⁴⁻³⁶

Indications. Steroid injection is the treatment of choice for this condition. US guidance is optional.

Corticosteroid dose. 15 to 20 mg methylprednisolone acetate (No. 25 or 27 needle).

Approach. The needle is aimed toward the radial styloid, which underlies the sheath (Fig. 69.9). The needle is then pulled back by the millimeter and injection is attempted. Successful injections distend the sheath of the abductor pollicis longus or extensor pollicis brevis (or both). Up to three injections given 3 weeks apart are allowed.

Precautions. The corticosteroid must remain within the sheath. Do not infiltrate grossly thickened sheaths because mycobacterial infection may be present.

Complications. Skin hypopigmentation and skin atrophy.

Fig. 69.8 Injection for right carpal tunnel syndrome.

Fig. 69.9 Injection for right de Quervain tenosynovitis.

Wrist extensor tenosynovitis

Indications. Sustained tenosynovitis in patients with RA and psoriatic arthritis, microcrystalline tenosynovitis. Failure of one injection is an indication for tenosynovectomy.

Corticosteroid dose. 15 to 20 mg methylprednisolone acetate. (No. 25 or 27 needle).

Approach. A direct US-guided injection is preferred (Figs. e69.9 and e69.10).

Complications. The extensor digital tendons are prone to spontaneous rupture in patients with RA. An intratendinous injection probably enhances this tendency. Whether to inject an extensor tendon sheath or proceed to tenosynovectomy should be discussed with a hand surgeon.

Ganglia

Indications. Local corticosteroids are highly effective in the treatment of routine dorsal ganglia. Ganglia within the carpal tunnel, those that impinge on neurovascular structures, and those larger than 3 cm in diameter should be injected under US guidance³⁷ or treated surgically.

Corticosteroid dose. Depends on the lesion; usually 15 to 20 mg methylprednisolone acetate (No. 20 or 18 needle; thinner needles may become clogged).

Approach. The needle is aimed at the center of the lesion, which is aspirated before injection. Ganglia contain a viscous, translucent fluid. Fluid with other characteristics indicates that the lesion is not a ganglion; the fluid should therefore be cultured and inspected for crystals.

US guidance for ganglia injections is especially valuable with deeply located lesions or when they are close to other structures that may be punctured incidentally (e.g., tendons, peripheral nerves or vessels) (Fig. e69.11 and Fig. 69.10a and b).

Precautions. With ganglia in the wrist and anatomic snuffbox, rule out radial artery aneurysm, which mimics a ganglion. These lesions are expansile with the pulse, as opposed to the focal pulsation caused by a normal adjacent radial artery.

Complications. None.

ELBOW REGION

Elbow (joint)

Indications. Aspiration for acute arthritis, injection for RA, and psoriatic arthritis.

Corticosteroid dose. 30 to 40 mg methylprednisolone acetate (No. 22, 25, or 27 needle). Aspiration should be attempted before injection. For aspiration alone, use a No. 20 or 18 needle, depending on the suspected diagnosis. US guidance is optional.

Approach for blind injections. Two entries are commonly used; for both entries the elbow is held flexed at 90 degrees.

—Inferolateral approach. The midpoint cleft between the tip of the olecranon and the lateral epicondyle is palpated. The needle is then inserted perpendicularly and aimed at the center of the joint.

—Lateral approach. The radiocapitellar joint may be entered from the side just proximal to the radial head. The needle is passed perpendicular to the skin between the two bones (Fig. 69.11).

Fig. 69.10 Ultrasound-guided injection of a ganglion cyst at the anterior aspect of the elbow (i.e., radiohumeral joint) with the needle parallel to the long axis of the transducer (a) or perpendicular to the long axis of the transducer (b). The hyperechoic needle (a; arrowhead) or the tip of the needle (b; arrowhead) is seen inside the lesion.

Fig. e69.9 The needle is inserted adjacent to the transducer and directed to the sheath of the fourth extensor compartment of the wrist.

Fig. e69.10 Same patient as in [Figure e69.9](#). On the ultrasound image the needle (arrowhead) is introduced into the hypoechoic extensor tenosynovitis. lu, lunate; sc, scaphoid; tr, triquetrum.

Fig. 69.11 Lateral (radiocapitellar) injection of the left elbow in a patient with rheumatoid arthritis.

If palpation-guided aspiration of the elbow joint is not successful, US-guided arthrocentesis can be carried out from an anterior or posterior recess, depending on the location and characteristics of the effusion. The brachial artery and median and radial nerves can easily be identified and avoided with the anterior needle route.

Precautions. No neurovascular structures are located in the vicinity.

Complications. None.

Olecranon bursa

Indications. For the diagnosis of effusion and for the treatment of refractory aseptic bursitis (traumatic or microcrystalline). A negative bursal fluid culture is required before steroid injection. US guidance is not necessary.

Corticosteroid dose. 20 mg methylprednisolone acetate (No. 20 or 22 needle). Empty the bursa before injection.

Approach. Lateral through normal skin and aimed at the center of the bursa (Fig. e69.12).

Precautions. Taps at the tip of the bursa may create a chronic leak. Medial entries may damage the ulnar nerve.

Complications. Injection of 20 mg methylprednisolone acetate has not caused complications.

Lateral epicondylar syndrome, or tennis elbow, and medial epicondylar syndrome, or golfer's elbow^{38,39}

Indications. Failure of conservative treatment. To shorten the symptomatic period (with the caveat that the long-term outcome may be worse in injected than in uninjected patients). US guidance is not necessary.

Corticosteroid dose. 10 to 20 mg methylprednisolone acetate (No. 25 or 27 needle).

Approach for the lateral epicondyle. At the most tender point (Fig. 69.12), pass the needle until contact with the periosteum is made and infiltrate with 1 mL lidocaine. Failure to eradicate pain on resisted wrist dorsiflexion indicates the wrong injection site; reposition the needle and reinfiltrate with lidocaine. The corticosteroid should be infiltrated deeply at the enthesis and radially within the proximal part of the tendon.

Approach for the medial epicondyle. Aim the needle toward the distal portion of the medial epicondyle where the wrist flexor muscles insert.

Avoid injecting the posterior surface of the epicondyle to stay away from the ulnar nerve (Fig. e69.13).

Precautions. Avoid injecting too superficially.

Complications. Transient increase in pain in 20% to 40% of patients. Repeated corticosteroid infiltrations may result in chronic pain.

SHOULDER REGION

Shoulder (glenohumeral joint)

Indications. Aspiration for acute arthritis; injection for RA, spondyloarthritis, and the initial stages of frozen shoulder⁴⁰; viscosupplementation for OA. US guidance is necessary for the latter indication and desirable for all of them.

Fig. 69.12 Injection for right tennis elbow (lateral epicondylar syndrome).

Fig. 69.13 Posterior approach to the right shoulder in a patient with a frozen shoulder.

Corticosteroid dose. 40 to 80 mg methylprednisolone acetate (No. 22 needle). Aspiration should be attempted before injection. For frozen shoulder, injection into the joint may be difficult because of the capsular restriction. For aspiration alone, use a No. 20 or larger needle.

Approach for blind injection. Two entries are described: the posterior approach, which is preferred by the authors, and the anterior approach.

—**Posterior approach** (Fig. 69.13, Figs. e69.14 and e69.15). With the patient sitting, the posterior margin of the acromion is palpated. The needle is then inserted posteroanteriorly 1 cm below and 1 cm medial to the posterior corner of the acromion and aimed toward the coracoid process until bone is touched at the articular space.

—**Anterior approach.** Again, the patient should be sitting with the arm hanging at the side of the body, elbow flexed 90 degrees, and forearm in the sagittal plane. The needle is inserted anteroposteriorly 1 cm distal and 1 cm lateral to the coracoid process. Once the bone is touched, the forearm is very gently and passively brought into internal rotation as the needle is pushed into the articular space.

The glenohumeral joint is usually injected from a posterior approach under US guidance. The needle is directed to the posterior synovial recess located at the superior angle of the posterior labrum.

Precautions. Use a chair with armrests; watch for fainting.

Complications. Vasovagal syndrome. Misplaced anterior injections may encounter neurovascular structures.

Fig. e69.11 Transverse ultrasound image of a scapholunate ganglion.

Fig. e69.12 Lateral needle entry for olecranon bursitis.

Fig. e69.13 Injection for right golfer's elbow (medial epicondylar syndrome).

Fig. e69.14 Posterior approach to the right shoulder, back view.

Fig. e69.15 Posterior approach to the right shoulder, superior-lateral view.

Acromioclavicular joint

Indications. Aspiration for acute arthritis; injection for OA, RA, and spondyloarthritis. US guidance is not required.

Corticosteroid dose. 10 to 20 mg methylprednisolone acetate (No. 25 or 27 needle). Aspiration should be attempted before injection. For aspiration alone use a No. 20 needle.

 **Approach.** Aim the needle perpendicular to the skin into the articular cleft; aspirate or inject to distend the joint (Fig. e69.16).

Precautions. The procedure is difficult because the acromioclavicular joint space is narrow and has a partial meniscus.

Complications. None.

Subacromial bursa¹⁰

 **Indications.** Injection may be indicated for rotator cuff tendinopathy and inflammatory and microcrystalline bursitis. US guidance is highly desirable (Figs. e69.17 and e69.18).

Corticosteroid dose. 30 to 40 mg methylprednisolone acetate (No. 22 or 25 needle).

Approach for blind injection. The needle is inserted laterally near the posterior angle of the acromion and aimed anteromedially while ensuring that it passes under the anterior half of the acromion. Easy flow and bulging outlining the bursa indicate bursal injection.

Precautions. None.

Complications. None.

Note: Only about 50% of blind subacromial bursa injections fall on target.

Rotator cuff calcific tendinitis

In patients with calcific tendinitis of the rotator cuff who do not respond to blind corticosteroid injections, US-guided puncture of the calcifications combined with local corticosteroid injection can be a successful therapeutic alternative.⁴¹ The needle should be directed to the subdeltoid bursa under continuous US guidance. After the bursa is anesthetized with lidocaine, the needle is introduced through the tendon until the calcium deposit is reached. Fragmentation and aspiration of at least part of the calcium deposit and later bursal and peritendinous corticosteroid injection are carried out. Calcification lavage can be facilitated by using two needles for the procedure.

HIP REGION

Hip joint⁴²

Indications. Diagnosis of septic arthritis, including the differential diagnosis of septic arthritis versus aseptic loosening in a prosthetic hip; viscosupplementation. US guidance is required.

Corticosteroid dose. Although the procedure is generally performed for diagnosis, there are proponents of steroid injection or, preferably, viscosupplementation for advanced hip osteoarthritis. The dose is 40 to 60 mg methylprednisolone acetate mixed with 3 mL of 1% lidocaine (No. 22 needle). Aspiration should be attempted before injection.

Approach. US guidance is required (see Fig. 69.2a and b).

Precautions. The danger of injuring the femoral neurovascular bundle is averted by guidance with US.

Complications. None.

Iliopsoas bursa

Indications. Painful iliopsoas bursitis⁴³ and bursal distention causing neurovascular compression.

Corticosteroid dose. 30 to 40 mg methylprednisolone acetate mixed with 3 mL of 1% lidocaine (No. 22 needle). Aspiration should be attempted before injection.

Approach. US guidance, as for the hip.

Precautions. As for the hip.

Complications. None.

Trochanteric syndrome

Indications. Lateral hip pain with trochanteric tenderness.⁴⁴ US guidance is not required. However, US allows differential diagnosis between trochanteric bursitis and gluteus tendinopathy-enthesopathy and, if present, facilitates injection inside the bursa.

Corticosteroid dose. 40 mg methylprednisolone acetate mixed with 5 mL of 1% lidocaine (No. 22, 1.5-inch needle; a longer needle may be required for obese patients).

Approach. With the patient lying on the opposite side, the greater trochanter is identified by distal-to-proximal palpation along the femur. The point of maximal tenderness is usually located at the posterior corner of the trochanter. The needle is inserted vertically until contact with the periosteum. The mixture of corticosteroid and lidocaine should then be infiltrated radially to cover the base of a cone 3 cm in diameter, half on bone and half in the proximal soft tissues (Fig. e69.19).

Precautions. The needle should be of sufficient length to reach bone.

Complications. None.

KNEE REGION

Knee (joint)

Indications. For diagnosis of any joint effusion; for corticosteroid injection in patients with RA, spondyloarthritis, OA, and occasionally, crystal-induced synovitis. For viscosupplementation, US guidance is not required.

Corticosteroid dose. 40 to 80 mg methylprednisolone acetate (No. 22 needle). Aspiration should be attempted before injection. For aspiration alone use a No. 20 or 18 needle depending on clinical suspicion.

Approach. Lateral, with the needle aimed at the patellar undersurface midway between the upper and lower poles of the patella⁴⁵ (Fig. 69.14a). When clinical attempts to aspirate a knee effusion are unsuccessful, confirmation of synovitis and guidance of the procedure can be achieved with US. The parapatellar recesses are more accessible to US-guided injection than the suprapatellar recess is (see Fig. 69.14b and c).

Precautions. Beware of superimposed septic arthritis in patients with RA. Postpone injection of an acutely inflamed joint until a negative synovial fluid culture result becomes available.

Complications. None.

Baker cyst

With very large cysts, direct aspiration through a large-bore needle followed by instillation of a corticosteroid is appropriate. US guidance is highly desirable (Fig. 69.15).

Medial knee pain and pes anserinus syndrome

Indications. Pain in the pes anserinus area.^{46,47} US guidance is not required.

Corticosteroid dose. 20 to 40 mg methylprednisolone acetate mixed with 2 to 3 mL lidocaine (No. 22 needle).

Approach. The injection site is best determined by following the medial tendinous border of the thigh (semitendinosus tendon), with the knee in semiflexion, to the tibia, where a mark is placed. The knee is then brought to extension and the needle inserted perpendicularly until contact with the tibia (Fig. 69.16). An area 3 cm in diameter is infiltrated adjacent to the periosteum.

Precautions. Paresthesias extending along the medial aspect of leg indicate engagement of the saphenous nerve; reposition the needle.

Complications. None.

ANKLE AND FOOT

Ankle (joint)

Indications. As for the knee. US guidance is preferable⁴⁸ (see Fig. 69.1).

Corticosteroid dose. 40 to 60 mg methylprednisolone acetate (No. 22 or 25 needle). Aspiration should be attempted before injection. For aspiration alone use a No. 20 needle.

Approach for blind injection. With the patient supine on the examination table, seek the cleft between the tibia and talus by gently flexing and extending the foot. Insert the needle vertically medial to the anterior tibialis tendon (Fig. e69.20).

The lateral and medial tibiotalar recesses, with avoidance of vessels and tendons, are the usual routes for US-guided injections into the ankle.

Precautions. Avoid the dorsalis pedis artery.

Complications. None.

Fig. e69.16 Injection of a painful acromioclavicular joint in a patient with osteoarthritis.

Fig. e69.17 Ultrasound-guided direct injection into the subacromial bursa.

Fig. 69.16 Injection for right pes anserinus syndrome.

Fig. 69.17 Aspiration of the left first metatarsophalangeal joint for gout.

Subtalar joint

Indications. As for the knee. US guidance is optional.

Corticosteroid dose: 20 to 30 mg methylprednisolone acetate (No. 22 needle). Aspiration should be attempted before injection. For aspiration alone use a No. 20 needle.

Approach. By gently inverting and everting the foot, find the soft cleft (sinus tarsi) anterior to the lateral malleolus. Insert the needle perpendicularly toward the tip of the medial malleolus. Aspiration of fluid proves an articular insertion. Inject under low pressure (Fig. e69.21).

Precautions. This procedure should be performed only by health professionals with a thorough knowledge of anatomy.

Complications. None.

Metatarsophalangeal joints

Indications. Aspiration for the diagnosis of gout (usually the first metatarsophalangeal joint). Injection for hallux rigidus, RA, and spondyloarthritis. US guidance is optional.

Corticosteroid dose. 10 to 20 mg methylprednisolone acetate (No. 22, 25, or 27 needle). Attempt aspiration before injection. For aspiration alone use a No. 22 needle.

Approach for blind injection. Dorsal, lateral, or medial to the extensor tendon. Slight passive plantar flexion facilitates the procedure (Fig. 69.17, Figs. e69.22 and e69.23).

Precautions. None.

Complications. None.

Fig. e69.20 Aspiration of the right tibiotalar (ankle) joint in a patient with gout.

Fig. e69.21 Injection of the talocalcaneal joint (subtalar) in a patient with rheumatoid arthritis.

Fig. e69.22 Aspiration of second metatarsophalangeal joint for gout.

Fig. e69.23 Aspiration of fifth metatarsophalangeal joint for gout.

Fig. 69.18 (a) Ultrasound-guided direct injection into the retrocalcaneal bursa. The needle is inserted adjacent to the transducer and perpendicular to its long axis. (b) On the ultrasound image, the tip of the needle (arrow) is hyperechogenic inside the retrocalcaneal bursitis. B, bursa; cal, calcaneus.

Retrocalcaneal bursa

Indications. Refractory Achilles tendon enthesis, organ inflammation in spondyloarthritis, RA. Whenever possible this procedure should be performed under US guidance (Fig. 69.18a and b).

Corticosteroid dose. 15 to 20 mg methylprednisolone acetate (No. 22, 25, or 27 needle or butterfly). Aspiration should be attempted before injection. The presence of fluid (usually a trace) proves intrabursal location of the needle.

Approach for blind injection. Posterior approach.⁴⁹ The patient lies prone on the examination table with the foot outside the mattress. Allow calf relaxation. A 13-mm No. 27 insulin needle may be best suited for this procedure. The needle is advanced vertical to the skin, transtendinously, and aimed at the posterior superior calcaneal angle.

Precautions. This procedure should be performed only by health professionals with a thorough knowledge of anatomy.

Complications. Tendon rupture is possible and more than one reinjection is discouraged.

Posterior tibialis tendon sheath

Indications. Posterior tibialis tenosynovitis in patients with RA and spondyloarthritis; tarsal tunnel syndrome. US guidance is highly desirable (Fig. 69.19).

Corticosteroid dose. 20 to 30 mg methylprednisolone acetate (No. 22 or 25 needle).

Approach for blind injection. The patient lies supine with the injected leg resting on the contralateral knee. Have the patient invert the foot to identify the posterior tibialis tendon, which tents the skin. The needle is inserted tangentially, three fingerbreadths proximal to the tip of the medial malleolus. Inject under low pressure. Fluid may be seen and felt distending the sheath.

Precautions. Aspirate first to make sure that the posterior tibial artery has not been punctured. Plantar paresthesias indicate engagement of the posterior tibial nerve. This procedure should be performed only by health professionals with a thorough knowledge of anatomy.

Complications. The posterior tibialis tendon is prone to spontaneous rupture in patients with RA. A misplaced (intratendinous) injection probably enhances this tendency.

Plantar fascia calcaneal entheses^{50,51}

Indications. Refractory plantar fasciitis in patients with spondyloarthritis. US guidance is optional.

Corticosteroid dose. 20 to 30 mg methylprednisolone acetate diluted with 2 mL lidocaine (No. 22 needle).

Approach for blind procedure. Medial, needle parallel to the plantar skin 2 cm deep to the plantar surface. Aim the needle into the medial plantar tubercle of the calcaneus. Resilience indicates a fascial location. Relocate the needle and inject deeply and superficially to the fibrous fascia (Fig. e69.24).

Precautions. This procedure should be performed only by health professionals with a thorough knowledge of anatomy.

Complications. Repeated infiltrations result in fat atrophy and pressure-induced plantar heel pain. Rupture of the plantar fascia may also occur. Discourage more than one reinjection (2 to 3 weeks after the initial injection).

Fig. 69.19 Ultrasound-guided direct injection for tenosynovitis of the tibialis posterior tendon. The needle (arrowhead) is inserted within the distended tendon sheath (TS). mm, medial malleolus; tpt, tibialis posterior tendon.

Intermetatarsal bursae

Indications. Intermetatarsal bursitis in patients with RA (two or more toes spread apart). US guidance is optional.

Corticosteroid dose. 20 to 30 mg methylprednisolone acetate (No. 25 or 27 needle).

Approach. Dorsal to plantar with the needle aimed toward the space in between the metatarsal heads (Figs. e69.25 and e69.26).

Precautions. Plantar fat atrophy is minimized by using an insulin needle.

Complications. None.

Morton neuroma⁵²

Indications. Morton neuroma. US guidance is optional.

Corticosteroid dose. 20 to 30 mg methylprednisolone acetate mixed with 1 mL lidocaine (No. 22 or 25 needle).

Approach for blind procedure. Through the web space on the plantar side (Fig. 69.20). The needle is advanced in a distal-to-proximal direction and aimed at the neuroma (technique taught to one of the authors by Lilia Andrade-Ortega, MD, Mexico City).

Precautions. Inject under low pressure. This procedure should be performed by health professionals with a thorough knowledge of anatomy.

Complications. None are expected; up to two reinjections 2 to 3 weeks apart are allowed.

INTRALESIONAL CORTICOSTEROID TREATMENT

Intralesional corticosteroid treatment is sometimes used for discoid lupus,⁵³ medical treatment of rheumatoid nodules⁵⁴ (Fig. e69.27), nodular fasciitis,

Fig. e69.24 Injection for calcaneal plantar fascia enthesopathy.

Fig. e69.25 Intermetatarsal bursitis in a patient with rheumatoid arthritis. The third and fourth toes are spread apart along with soft tissue tenderness between the metatarsal heads.

Fig. e69.26 Same patient as in Figure e69.25. For steroid injection, the needle is inserted vertically into the intermetatarsal space.

Fig. e69.27 Corticosteroid injection of a rheumatoid nodule (see text for technique).

Fig. 69.20 Injection for Morton neuroma, right foot, third web space.

occasionally Sweet syndrome,⁵⁵ granulomatous disease including Crohn disease affecting the oral cavity,⁵⁶ tracheal granulomas in patients with Wegener granulomatosis,⁵⁷ eosinophilic granuloma of the skin,⁵⁸ and inflammatory eye conditions unresponsive to oral or parenteral agents.⁵⁹

Acknowledgments

The authors acknowledge the valuable contributions and teachings of Prof. Juan J. Canoso, who was a coauthor of this chapter in the previous edition.

We thank our patients for generously allowing us to take pictures during aspiration or injection procedures for the benefit of others. We also thank Ana Cruz, MD, and Felix Cabero, MD, from the Department of Rheumatology of the Hospital Severo Ochoa for their help in obtaining pictures of the US-guided injection methods.

Perioperative care of patients with rheumatic disease

■ C. RONALD MacKENZIE ■ STEPHEN A. PAGET

- Careful preoperative evaluation, patient selection, and postoperative care are essential; coordination between the surgeon and rheumatologist is necessary.
- Orthopedic surgery can relieve pain and improve function.
- Joint replacement surgery, including hip, knee, ankle, shoulder, elbow, and wrist replacement, has been successful.
- Arthroscopy, synovectomy, osteotomy, and fusion procedures might be indicated in selected patients.

It is important for rheumatologists to understand the processes underlying the decision to proceed with orthopedic surgery and the needs of patients postoperatively. This chapter describes a stepwise approach to the preoperative medical evaluation and assessment of surgical risk in patients with chronic rheumatic conditions.

INDICATIONS FOR ORTHOPEDIC SURGERY

Indications for elective orthopedic surgery are refractory and intolerable pain and disability attributable to a well-defined and significant pathologic state that has become intolerable to the patient. The final decision for surgery requires agreement between the patient, the orthopedic surgeon, and often the physician that the positive effects of surgery outweigh the potentially negative consequences, a complex balance, especially in frail older patients with significant comorbid conditions such as rheumatic disease. Two of the most frequently performed major orthopedic procedures in the rheumatic disease population are total joint replacement and spine surgery. In addition to the broad indications just mentioned, the latter is indicated in those with a progressive or incapacitating neurologic problem that demands immediate treatment, such as severe radiculopathy (for example, acute footdrop) or myelopathy.

Patients and their clinicians have different perspectives that need to be considered in detail (Box 70.1).

PREOPERATIVE ASSESSMENT

Influence of changing medical practice

As a consequence of medical advances, as well as financial and resource constraints, there has been a substantial trend toward performing surgery in the ambulatory, outpatient setting, which in orthopedic practice reflects the growth in arthroscopic techniques.^{1,2} The interval between the decision for outpatient surgery and performance of the operation thus allows time for the multiple detailed assessments outlined in Box 70.1.

Although the efficacy of preoperative assessment has not been definitively established,^{3,4} the aging and increasing complexity of modern-day surgical patients justify the process. The Australian Incident Monitoring Study⁵ revealed that 11% of preoperative assessments were considered either inadequate or incorrect and contributed to 3% of the adverse postoperative events, with the majority being considered major morbidity and almost all of which were preventable. In another study of anesthetic-related deaths, more than a third of deaths involved suboptimal preoperative assessment

and management.⁶ Delays in surgery, subsequent complications, and unexpected postoperative admissions to higher levels of care have been shown to be reduced by preoperative evaluation.⁷ Furthermore, anxiety, pain, length of stay, and patient satisfaction are favorably influenced by preoperative evaluation and enhanced by patients meeting with the anesthesiologist preoperatively.⁸

Key desired characteristics of perioperative care

The literature supports various core principles that underlie effective medical consultation, including the following⁹:

1. Consultation by either a physician or appropriately trained health care professional, which increasingly in some health care systems involves adopting a comanagement strategy for the patient's postoperative care or in some instances assuming full responsibility for the patient after completion of the surgery
2. Particular emphasis on the challenges posed by the elderly with their comorbid conditions and restricted physiologic reserve (homeostenosis)

History and physical examination

A complete history and physical examination constitute the bedrock of preoperative evaluation and also provide justification for any necessary ancillary testing. The indication for surgery should be ascertained and considered alongside the magnitude, nature, and urgency of the selected procedure. Previous experience with surgery and anesthesia and the presence, severity, and stability of all comorbid conditions should be established. All prescription and over-the-counter medications, including the use of herbs and supplements, should be recorded along with their dosages and dosing schedules. The use of tobacco, alcohol, and other drugs should also be documented, as should the patient's allergic history.

In the preoperative context the physical examination should focus on patient characteristics that might have an adverse impact on the patient's postoperative course. Among the areas for specific focus is the patient's body mass index, which is not only associated with other chronic diseases but is also an independent risk factor for problems with surgery. Obesity, large neck circumference, and hypertension predict obstructive sleep apnea (OSA), an important but underappreciated problem in the postoperative setting. Second, careful auscultation of the heart is important because the presence of third and fourth heart sounds may indicate congestive heart failure, and depending on its nature and severity, valvular heart disease may compromise cardiac function at times of physiologic stress, such as surgery.

Laboratory studies

The role of routine preoperative investigations is unclear,¹⁰ with some evidence suggesting that routine testing may actually be harmful.¹¹ Abnormalities in test results are of much greater significance in patients with clinical findings¹² suggesting new or persistent abnormalities.¹³ An extensive literature has failed to demonstrate that routine testing improves surgical outcomes.¹⁴ In one study, guidelines designed to reduce preoperative testing did not result in untoward perioperative events or an increase in test ordering.¹⁵ In particular, in studies involving healthy patients undergoing minor procedures, routine preoperative laboratory testing appears to be unnecessary.^{16,17} Nonetheless, depending on the patient and the nature and magnitude of the planned surgery, a number of investigations may be considered appropriate and are commonly performed before major surgery (Table 70.1).

BOX 70.1 PERSPECTIVES OF PATIENTS AND THEIR CLINICIANS**Patient perspectives**

Uniformity of opinion that my pain and disability are not improved by conservative therapies?
 Risks associated with surgery and how they can be reduced given my health status?
 Specific needs related to underlying joint disease that increase the chance for complications?
 Requirements regarding current medications both preoperatively and postoperatively?
 Surgeon experience and expertise?
 Ability to communicate with the surgeon and opportunity to speak to a recent patient?
 Track record of the hospital in performing this operation, including medical and rehabilitation support?
 Support at home after the surgery?

Surgeon perspectives

Confidence in the type and extent of the musculoskeletal problem and exclusion of referred pain, infection, or fracture?
 Appropriate level of unsuccessful conservative care?
 Severity justifies surgery to achieve the patient's desired outcome?
 Are the patient's expectations appropriate?
 Patient's medical and psychological status?
 Any increased risk for thromboembolic phenomena and what prophylaxis is needed?
 What other potential complications might this patient face?

Need for another physician's opinion before surgery?
 Antibiotic prophylaxis needed and any allergy?
 Need for a rehabilitation center before discharge home and the nature of the home setting to ensure an optimal outcome?

Rheumatologist/internist perspective

Formal assessment of the musculoskeletal problem causing the pain and disability?
 Medical and psychological preparation for the planned surgery?
 Need to change the medication regimen?
 Preoperative assessments, such as to determine any increased risk for cardiovascular complications?
 Specific needs of patients with diabetes or those treated with corticosteroids?
 Need for thromboembolic prophylaxis and nature?
 Continuity of care and communication with the surgical team about problems arising in the hospital?

Anesthesiologist perspective

Communication with others involved in the patient's care or medical status/
 Discussion of the type of anesthesia with the patient and the medical and surgical team?
 Patient's use of current medications preoperatively?
 Specific issues related to diabetes or treatment with corticosteroids?
 Specific monitoring needed perioperatively for patients with cardiac, pulmonary, neurologic, or other medical problems?

TABLE 70.1
Recommendations for laboratory testing before elective surgery

Test	Incidence of abnormalities that influence management	LR[+]	LR[-]	Indications
Hemoglobin	0.1%	3.3	0.90	Anticipated major blood loss or symptoms of anemia
White blood cell count	0.0%	0.0	1.00	Symptoms suggest infection, myeloproliferative disorder, or myelotoxic medications
Platelet count	0.0%	0.0	1.00	History of bleeding diathesis, myeloproliferative disorder, or myelotoxic medications
Prothrombin time	0.0%	0.0	1.01	History of bleeding diathesis, chronic liver disease, malnutrition, or recent or long-term antibiotic use
Partial thromboplastin time	0.1%	1.7	0.86	History of bleeding diathesis
Electrolytes	1.8%	4.3	0.80	Known renal insufficiency, congestive heart failure, or medications that affect electrolytes
Renal function	2.6%	3.3	0.81	Age >50 yr, hypertension, cardiac disease, major surgery, or medications that may affect renal function
Glucose	0.5%	1.6	0.85	Obesity or known diabetes
Liver function tests	0.1%			No indication. Consider measurement of albumin for major surgery or chronic illness
Urinalysis	1.4%	1.7	0.97	No indication
Electrocardiogram	2.6%	1.6	0.96	Men >40 yr, women >50 yr, known CAD, diabetes, or hypertension
Chest radiograph	3.0%	2.5	0.72	Age >50 yr; known cardiac or pulmonary disease, symptom, or result of examination suggests cardiac or pulmonary disease

CAD, coronary artery disease; LR, likelihood ratio.

Assessment of operative risk

Individual patient prediction

Rating systems have been developed to identify patients in whom postoperative complications are most likely to develop.

The best known and most widely used is the *American Society of Anesthesiologists Physical Status Scale*, an index that is highly correlated with a patient's postoperative course (Table 70.2).¹⁸ First proposed in 1941, a revision of the scale became the Physical Status Scale. Though criticized for the vagueness of its criteria, it has proved to be an extraordinarily durable and useful assessment tool. Nonetheless, the search for more robust prediction methodologies has continued, and considerable success has been achieved in the assessment of cardiac risk specifically.

The landmark work of Goldman on assessment of cardiac risk in patients undergoing noncardiac surgery can now be seen as having ushered in the field of perioperative medicine.¹⁹ The *Goldman Cardiac Risk Index* has undergone extensive study and subsequent revision.²⁰⁻²² The *Revised Cardiac Risk Index* is the most widely used scoring system to date (Table 70.3). It is

simple to calculate, with 1 point being assigned for each of six independent risk factors for major cardiac complications in patients undergoing noncardiac surgery (Table 70.4).

However, the search continues to develop more global indicators of risk. Holt and Silverman proposed a *resilience* score for organ systems compromised by an underlying disease process.²³ An overall resilience score for a given organ system is derived by adding the standard American Society of Anesthesiologists score to a surgical complexity score (rated 1 to 5). The maximum score is 10, and the higher the score, the more likely that a given organ system will suffer injury or fail when surgically stressed. Once calculated, the individual scores for each organ system assigned a score of 3 or higher can be added, with the total reflecting the impact of multisystem disease.

Risk from the epidemiologic level

Recent epidemiologic studies by Memtsoudis and colleagues^{24,25} provide an interesting context from which to examine trends in the performance and outcomes of orthopedic surgery, as well as useful information relevant to

TABLE 70.2
American Society of Anesthesiologists Physical Status Scale

Level of risk	Presence of a systemic disturbance	Associated surgical mortality
I	Absent	0.2%
II	Mild	0.5%
III	Severe/not incapacitating	1.9%
IV	Incapacitating/threat to life	4.9%
V	Moribund/survival <24 hr without surgery	N/A
E (subdesignation)	Emergency surgery	Doubles risk

N/A, not applicable.

Data from Prouse G, Rotzenhofer-Correnda B, Pierer G, et al. Can ASA grade or Goldman's cardiac risk index predict peri-operative mortality? A study of 16,227 patients. *Anaesthesia* 1997;52:203-6.

TABLE 70.3
Revised Cardiac Risk Index

High-risk surgery	Intraperitoneal, intrathoracic, suprainguinal, vascular
History of ischemic heart disease	Myocardial infarction, positive stress test, angina, nitrate therapy, pathologic Q waves
History of congestive heart failure	Congestive heart failure, pulmonary edema, paroxysmal nocturnal dyspnea, rales or S3 gallop, vascular redistribution on chest radiograph
History of cerebrovascular disease	Transient ischemic attack or stroke
Preoperative treatment with insulin	
Preoperative serum creatinine >2.0 mg/dL

assessment of perioperative risk. In an ongoing series of studies, observations concerning the outcome of specific orthopedic procedures are drawn from two large national data sets: the National Hospital Discharge Survey, which is composed of medical information collected annually since 1965 by the National Center for Health Statistics (a database of inpatient utilization), and the National Inpatient Sample, the largest annual all-payer database in the United States. The power of these studies is derived from the enormous size of the archive, which in one study involved nearly 7 million patient discharges.²⁴

Thus far this work has focused on lower extremity arthroplasty, specifically, the outcomes, complications, and mortality after total joint replacement (unilateral, bilateral, revision). Several broad themes relevant to perioperative care can be derived from the analysis. First, performance of total joint arthroplasty has increased over time, and trends in the prevalence of comorbid conditions has confirmed an increase in the frequency of hypertension, diabetes mellitus, hypercholesterolemia, obesity, pulmonary disease,

and coronary artery disease over time.²⁴ Overall complication rates have declined despite decreasing length of stay, except in the case of bilateral procedures. Indeed, in patients undergoing bilateral total joint arthroplasty, procedure-related complication rates were higher than in those undergoing unilateral procedures despite a younger average age and lower burden of comorbidity.²⁵ Mortality after total joint arthroplasty of the hip and knee was most strongly correlated with postoperative pulmonary embolism and stroke.²⁴ Preoperative risk factors for in-hospital mortality were revision total joint arthroplasty, advanced age (>85 years), and the presence of specific comorbid conditions (predominately dementia and renal and cerebrovascular disease). A steady decrease was noted in the risk for death over the time of the study (1990 to 2004). Extending this line of inquiry, Stundar and associates²⁶ compared perioperative outcomes in patients with rheumatoid arthritis (RA) and osteoarthritis after total hip replacement and reported higher rates of pulmonary and infectious complications in rheumatoid patients that resulted in longer lengths of stay and higher cost.

Finally, a recent study of patients with systemic lupus erythematosus (SLE) undergoing surgery also demonstrated increased risk for perioperative adverse events,²⁷ although all-cause postoperative mortality was significantly higher in women with SLE. Stratified according to their risk for cardiovascular events, patients with SLE undergoing low- and high-risk procedures had worse outcomes. Curiously, those undergoing surgery of an intermediate nature did not, a relevant finding because most orthopedic surgery falls into the intermediate category.

ANESTHESIA IN PATIENTS WITH RHEUMATIC DISEASE

A variety of issues, including airway considerations, the site and anticipated duration of surgery, existing comorbidity, and the patient's emotional state, are important determinants of the type of anesthesia that should be used, whether invasive monitoring will be necessary, and the length of time that the patient will spend in the recovery room after surgery.

Type of anesthesia

General anesthesia and regional anesthesia are commonly used in the surgical treatment of patients with rheumatic disease. General anesthesia with endotracheal intubation may pose a particular danger in patients with RA or ankylosing spondylitis (see later discussion on the cervical spine). In patients with cervical spine instability or a rigid airway, fiberoptic intubation may be required. Regional anesthesia may take the form of local anesthesia for minor procedures, peripheral nerve block for surgery on the upper and lower extremities, and epidural/spinal anesthesia for arthroplasty involving the lower extremity.

Many orthopedic surgical procedures are well suited to regional anesthetic techniques. Some evidence suggests that regional anesthesia does reduce the incidence of major perioperative complications such as blood loss,²⁸ deep venous thrombosis, and pulmonary embolism, as well as postoperative respiratory events and death.²⁹ Furthermore, postoperative pain management, a significant problem for patients with a painful rheumatic disease, may be best managed with regional anesthetic approaches.³⁰ Peripheral nerve blocks using longer-acting anesthetics and infusion methodologies are another consideration because they provide both excellent intraoperative anesthesia and postoperative pain relief.³¹

Monitoring techniques

Patients undergoing major surgery should have continuous electrocardiographic and pulse oximetry monitoring intraoperatively. At the discretion of the anesthesiologist, arterial and Swan-Ganz catheter monitoring may be helpful in selected patients such as those undergoing bilateral joint replacement surgery or those with a history of previous cardiac disease.

Postoperative analgesia

Postoperative pain can be controlled with traditional intravenous delivery, intramuscular routes (systemic), and epidural analgesia. Epidural patient-controlled analgesia is very effective in controlling pain postoperatively and can aid in facilitating postoperative physical therapy, which is important in restoring a patient's range of motion after orthopedic surgery. This method also reduces systemic absorption of analgesics and thus reduces the problem of narcotic-induced respiratory depression. Parenterally administered non-steroidal antiinflammatory agents are a useful alternative to traditional analgesia after surgery and can be used to reduce narcotic requirements after

major surgery. These drugs should not be given to patients with common contraindications to nonsteroidal antiinflammatory agents such as peptic ulcer disease, renal disease, ischemic heart disease, and the concomitant use of anticoagulants.

More recently, a multimodal approach to pain management has been embraced because of increased awareness of the range and severity of undesirable adverse effects that can occur with traditional postoperative analgesia.^{32,33} Adverse effects are particularly common in elderly patients, who are prone to narcotic-induced delirium, respiratory depression, and constipation. Multimodal methods use an array of agents, including nonsteroidal antiinflammatory drugs (usually cyclooxygenase-2 [COX-2] inhibitors), steroids (Decadron), narcotics, and peripheral nerve blockade. Acetaminophen is not often used despite its recently approved intravenous preparation. Even more innovative approaches are being studied, such as placing an indwelling catheter in the knee to deliver a continuous infusion of local anesthetic (ropivacaine) after knee replacement surgery. Alternatively, a high-volume infiltration can be administered as a single dose.³⁴ With both these approaches patient-controlled analgesia is not required, and usually only small doses of narcotic are needed.

PERIOPERATIVE MANAGEMENT OF COMORBID MEDICAL CONDITIONS

Several important comorbid conditions are encountered perioperatively that can cause potential problems in patients with rheumatic disease.

Ischemic heart disease

The contribution of cardiovascular disease to the risk associated with noncardiac surgery cannot be overstated. The number of persons older than 65 years in the United States is set to increase by 25% to 35% over the next 30 years—the patient group in which the majority of orthopedic surgery is performed.³⁵ The annual number of noncardiac surgical procedures performed in this age group could increase from 6 to 12 million per year during this time. Many of them are major surgical procedures (intraabdominal, thoracic, vascular, and orthopedic), so postoperative cardiovascular morbidity and mortality will remain a primary focus of those involved in perioperative medicine. Fortunately, cardiovascular disease is the most investigated and well-documented domain of perioperative medicine. Practical guidelines to direct physicians involved in the assessment and care of patients with cardiac disease are widely recognized and updated regularly as new evidence comes to light.³⁵ Prediction rules using readily available clinical data have been studied extensively, validated, and disseminated to the practicing community.

The predictive value of routine clinical assessment, history and physical examination, electrocardiography, and chest radiography, supplemented by other noninvasive methodologies, is well established in identifying preexisting cardiac disease. Defining disease severity, stability, and previous treatment is also important because these factors, together with clinical characteristics such as age, functional capacity, comorbidity, and type of surgery to be performed, ultimately define postoperative risk. A series of factors may predict postoperative myocardial infarction, congestive heart failure, and death after orthopedic surgery.

The American College of Cardiology/American Heart Association guidelines for perioperative cardiovascular evaluation for noncardiac surgery³⁵ provide algorithms for every level of decision-making in the clinical setting, including indications for preoperative exercise stress testing and coronary angiography. Multiple modalities for noninvasive cardiac evaluation are available; some assess cardiac function under resting conditions, whereas others “stress” the patient (via exercise or pharmacologic induction of physiologic stress). In patients with high exercise tolerance in their daily lives, little useful information is likely to be gained from such testing. In others, such as chronically ill patients with rheumatic disease, evaluation of cardiac function preoperatively may be useful because the illness may limit the natural physical “stress.” Such decisions should be made on an individual basis. Many studies have examined the correlation between impairment of left ventricular function and postoperative cardiac complications. However, most postoperative complications occur in patients with a left ventricular ejection fraction of less than 35%. Although this observation links such cardiac phenomena as ischemia, congestive heart failure, and death to impaired cardiac function, a resting echocardiogram has not proven a reliable predictor of postoperative ischemic events.^{36,37} Other noninvasive methods of detecting coronary artery disease that use exercise to improve sensitivity and specificity are widely available and covered in an extensive literature. Exercise stress testing, with or without nuclear imaging or

echocardiography, is widely employed to assess and detect coronary artery disease in general practice. Regardless of whether the method uses formal exercise (i.e., treadmill or bicycle) or pharmacologic (dipyridamole, adenosine) means for stress simulation, the goal of such testing is provocation of myocardial ischemia by increasing myocardial oxygen demand relative to supply. In these studies, fixed defects that do not change after exercise-induced redistribution of blood flow represent myocardial scar from previous infarction and have less predictive value for postoperative ischemic events. In patients with reversible abnormalities, cardiac risk increases with increasing size and number of reperfusion abnormalities. A meta-analysis of 68 studies involving 10,278 patients undergoing noncardiac surgery compared the predictive value of stress echocardiography and thallium imaging and showed that stress echocardiography had superior predictive capability for postoperative cardiac events.³⁸ Nonetheless, more than a third of the complications occurred in patients with negative test results. It remains unclear whether one approach to stress testing is definitively superior to another. They may all be reasonably good for preoperative assessment of risk, and the choice may be related to the patient's physical capacity to participate in stress induction and the availability of such testing. The former is particularly true in disabled rheumatic disease or orthopedic patients. The important question is not which test should be performed but which patients will benefit from such assessments?

Strategies to reduce cardiac risk during noncardiac surgery may involve medical therapy or invasive cardiac interventions performed preoperatively, alterations in anesthetic technique, and aggressive management of adverse hemodynamic developments intraoperatively and postoperatively. For an internist rheumatologist who evaluates a patient preoperatively, the relevant approach includes medical management, specifically, the use of β -blockers, antiplatelet agents, and statin therapy. The widespread use of cardiac stents has become an important preoperative management problem. On occasion, coronary revascularization is considered before noncardiac surgery.

The most significant advance in perioperative medical care is recognition of the protective role of β -blockade. β -Blockers protect the heart by improving myocardial oxygen balance by slowing the heart rate and reducing contractility. Slowing the heart rate has additional benefits—an improvement in diastolic filling while decreasing myocardial oxygen consumption. Though used widely in the treatment of coronary artery disease for decades, it was not until 1996 that a potential role of β -blockers in preventing postoperative cardiac complications was shown. Mangano and coworkers³⁹ examined the role of perioperative β -blockade in patients with known coronary artery disease or with significant risk factors. Patients were randomized to receive atenolol or placebo 7 days before surgery and for 1 month afterward. A significant reduction in cardiac events was noted postoperatively and remained significant for a 2-year period.⁴⁰ Subsequent work⁴¹ appeared to confirm the benefit of preoperative and postoperative administration of β -blockers in the noncardiac surgical setting, so its practice was widely promulgated. However, a large-scale randomized controlled trial has thrown this practice into question.⁴² This study, which involved 8351 patients at 190 centers across the globe, confirmed the findings of numerous clinical trials that prophylactic β -blockade significantly decreases the incidence of postoperative myocardial infarction. However, this benefit was negated by the higher incidence of death, stroke, clinically significant hypotension, and bradycardia, thus raising concern about the overall safety of this practice. This is the major current controversy in perioperative medicine and remains under active debate. The most prudent approach is to use perioperative β -blockade only in selected circumstances: for high-risk patients not already taking β -blockers, start therapy early (days to weeks before surgery), aim for a heart rate in the low 60-beat per minute range, and continue therapy for at least 1 week postoperatively.⁴³

Chronic aspirin (acetylsalicylic acid [ASA]) therapy for both the primary and secondary prevention of atherosclerotic cardiovascular disease and for the treatment of rheumatic disease is highly prevalent, so the use of ASA and other antiplatelet agents perioperatively is commonplace. Because of their perceived bleeding risk, use of such agents was, until recently, generally discontinued 5 days before surgery. As more evidence on the protective role of such therapy has come to light, the practice of discontinuing ASA therapy before surgery has been questioned. A meta-analysis of this issue demonstrated that ASA withdrawal preceded up to 10% of all acute cardiovascular events and that even though the frequency of ASA-related bleeding complications increased, the bleeding tended to be mild and not significant (except for intracranial surgery and transurethral resection of the prostate).⁴⁴ Other antiplatelet drugs (thienopyridines, clopidogrel, ticlopidine) are also in common use, although guidelines for perioperative application have not been established. Because of their longer half-life, general practice is to discontinue use of these agents at least 10 days before surgery.

A related problem of increasing prevalence is management of antiplatelet therapy in patients with intracoronary stents who are undergoing noncardiac surgery. Reports of stent thrombosis in the perioperative period in patients who have had such therapy discontinued preoperatively have raised concern about the attendant risks.⁴⁵ Such thrombosis is associated with high rates of myocardial infarction (up to 50%). Two major classes of stents are currently used, bare metal stents (BMSs) and drug-eluting stents (DESs). The latter contain drugs that prevent endothelialization of the stent and hence restenosis. Because the use of antiplatelet agents (usually dual antiplatelet therapy) significantly reduces the incidence of stent thrombosis, the protective influence of such medication is important. Furthermore, the risk for stent thrombosis varies with the type of stent used; BMSs are associated with lower risk when antiplatelet therapy is discontinued. The heightened risk for thrombosis with DESs can persist for up to a year. According to a recent advisory statement, for patients who require surgery and have had a DES placed in the preceding 12-month period, ASA alone should be maintained and use of the other antiplatelet agents stopped 7 to 10 days before surgery.⁴⁶

Last are the statins, medications known to have both lipid-lowering and antiinflammatory activity, the latter of which stabilizes coronary plaque, improves endothelial function, and inhibits platelet aggregation. Coupling these theoretic benefits with a number of clinical trials suggesting a cardioprotective effect perioperatively,⁴⁷ perioperative statin therapy should be continued despite the well-known potential complications of such therapy (hepatotoxicity, myositis, rhabdomyolysis).

Because of the effective treatment strategies now available, fewer patients with inflammatory arthritis or spondyloarthritis are undergoing orthopedic surgery. Nonetheless, some patients will still require surgery, and their particular cardiovascular risks need to be appreciated. Two converging lines of evidence confirm that patients with chronic rheumatic disease, particularly those with inflammatory disorders, are high-risk surgical candidates.^{48,49} Once viewed as a biochemically bland (though potentially clinically aggressive) lipid storage disease, observations derived from basic science now endorse the central role of inflammation in the initiation and progression of atherosclerosis.⁵⁰ The rheumatic disease literature is full of observations showing the contribution of the atherosclerotic process to the morbidity and mortality associated with these disorders.^{51,52} This is an important, if underappreciated relationship from the perspective of perioperative medicine. Moreover, from a clinical standpoint it may not be as obvious because the limited exercise capacity of these patients can mask the traditional signs and symptoms of coronary artery disease.

RA results in the premature development of arterial stiffening, atherosclerosis, and myocardial infarction. Congestive heart failure is likewise independently related to RA, possibly because of impaired left ventricular diastolic filling. Although effective control of disease activity may be beneficial in ameliorating vascular and myocardial disease, patients with severe disease are the most likely to have subclinical coronary disease. Like RA, SLE results in similar cardiovascular phenomena. Left ventricular hypertrophy may develop unrelated to traditional stimuli, probably because of inflammation-related arterial stiffening.⁵³ All COX-2-selective and traditional nonsteroidal antiinflammatory drugs increase the risk for ischemic heart disease and should be factored into the perioperative risk assessment.

Other cardiovascular diseases

Hypertension

The prevalence of hypertension perioperatively is 20% and it is associated with coronary artery disease, thus making it a risk factor for adverse outcomes after surgery. It has been shown to be one of five independent predictors of postoperative myocardial ischemia and one of three predictors of postoperative mortality. Nonetheless, clinical experience suggests that the magnitude of risk conferred by elevations in blood pressure alone appears to be small, and current practice is that surgery should not be postponed in patients with mild to moderate elevations in blood pressure. One large study of patients with chronically elevated blood pressure demonstrated no significantly different outcomes based on whether surgery was cancelled for those with diastolic blood pressure in the 110- to 130-mm Hg range.⁵⁴ Surgery in patients with greater elevations in blood pressure or those with major end-organ (cardiac, neurologic, renal) complications of the disorder should probably be cancelled until their pressure is under better control.

Valvular heart disease

Dysfunction of the cardiac valves is not uncommon in patients with connective tissue disease.⁵⁵ Beginning with the classic descriptions of the Libman-Sacks vegetations of SLE, regurgitation of the mitral valve has also been reported with RA.⁵⁶ Aortic valve disease, particularly aortic

insufficiency, has been reported in patients with HLA-B27-associated spondyloarthritis.⁵⁷ In these conditions aortic regurgitation has resulted from aortitis and subsequent dilatation of the aorta.⁵⁸ In addition to these associations, there is a high prevalence of aortic and aortic valve involvement in the systemic vasculitides, including granulomatous disorders, systemic vasculitis, giant cell arteritis, and Takayasu arteritis. In these conditions the inflammatory involvement of the great vessels results in aneurysmal dilatation of the aorta, aortic root dilatation and insufficiency, and in some cases, aortic dissection. Along with perioperative prothrombotic issues, antiphospholipid antibodies in SLE are associated with mitral valve nodules and significant mitral regurgitation, possibly because of activation of valvular endothelial cells.⁵⁹

Surgical risk in patients with valvular heart disease depends on the valve affected, as well as the nature and severity of the valvular lesion. The lesion conferring the highest perioperative risk is hemodynamically significant aortic stenosis; fortunately, it is relatively uncommon in conjunction with connective tissue diseases (though relatively prevalent in an aging surgical population). Mitral valve disease and aortic insufficiency, if not severe, are usually well tolerated, although any valvular disease associated with significant left ventricular dysfunction (New York Heart Association class 3 or 4) increases the risk associated with surgery. Therefore, patients with a significant cardiac murmur accompanied by signs or symptoms of left ventricular dysfunction should undergo an echocardiographic assessment preoperatively, particularly if major surgery is planned. Invasive hemodynamic monitoring perioperatively may be indicated in patients at high risk.

Conduction abnormalities and arrhythmias

Although cardiac conduction system disease and arrhythmias are a frequent marker of underlying cardiac or pulmonary disease, metabolic abnormalities, or drug toxicity, they are more frequently seen in patients with connective tissue disease. This is especially the case with scleroderma, in which myocardial fibrosis is thought to compromise the cardiac conduction system and lead to heart block and a wide range of electrocardiographic abnormalities and arrhythmias.⁶³ When patients with this and other connective tissue diseases are seen preoperatively with apparent conduction problems, the clinician should search for such conditions and institute corrective action, if possible, before surgery.

A problem that commonly arises is a patient with chronic atrial fibrillation who is being treated long-term with anticoagulation. Because the risk for embolic stroke in such patients without anticoagulation is low, it is safe to temporarily discontinue warfarin (Coumadin) for a sufficient period preoperatively to allow normalization of the prothrombin time and international normalized ratio (INR). Five days before surgery is generally sufficient, and reinstitution on the night of surgery is safe.

Pulmonary disease

Postoperative pulmonary complications are frequent and important adverse events in the postoperative period.^{60,61} One large study (1055 patients) reported a 2.7% incidence of pulmonary complications in patients thought to be at low to moderate risk; patients in whom such problems developed had a significantly longer length of stay (27.9 versus 4.5 days).⁶² Indeed, problems such as atelectasis, pneumonia, aspiration pneumonia, respiratory failure, and exacerbation of chronic obstructive lung disease (COPD) may have more severe consequences than cardiac disease and have been shown to be more predictive of long-term mortality.^{63,64} Smokers have up to a fourfold increased risk for postoperative pulmonary complications.⁶⁵ COPD is the most important patient-related factor predictive of postoperative complications, with a 6% to 28% risk for pulmonary complications developing after surgery.⁶² Asthmatics are also at increased risk if their disease is not well controlled preoperatively. The implication of chronic pulmonary disease in the perioperative setting is further underscored by the increased prevalence of cardiovascular disease in these patients.

Chronic pulmonary disease can be divided into three categories: asthma, obstructive lung disease, and restrictive lung disease. Chronic obstructive lung disease (chronic bronchitis, emphysema) and asthma are the two most prevalent forms of chronic pulmonary disease and are the pulmonary problems most commonly seen preoperatively. Characterized by reduced forced expiratory volume in 1 second (FEV₁) coupled with a normal to increased lung capacity, these conditions are important predictors of postoperative pulmonary complications, which may be pulmonary or nonpulmonary. The frequency of minor pulmonary complications (atelectasis, bronchitis) is increased in patients who smoke, have a chronic cough, or have abnormal results on spirometry. The risk for severe postoperative pulmonary complications (pneumonia, respiratory failure) is increased mainly in patients with marked impairment in lung function (FEV₁ <1.5 L).

Restrictive lung disease, though generally less common, deserves special mention because of its prevalence in patients with connective tissue disease. Defined by a symmetric decrease in FEV₁ and forced vital capacity (FVC) along with a reduction in total lung capacity, such restrictive patterns of lung spirometry are characteristic of the functional abnormality seen in patients with conditions such as RA, polymyositis/dermatomyositis, and SLE.⁶⁶

Risk factors for the development of postoperative pulmonary complications are divided into two categories: patient and procedure related.^{63,67} Patient-related risk factors include age, existing COPD, cigarette use, congestive heart failure, comorbid conditions, functional capacity, obesity, sleep apnea, and cognitive impairment. In contrast, procedure-related risk factors include the surgical site (increased complication rate with procedures near the diaphragm), duration of surgery, anesthetic technique, and emergency surgery. Even though attempts to develop an overall pulmonary predictive risk index similar to the Goldman Cardiac Risk Index have been unsuccessful, two separate pulmonary risk indices have been published, one to predict postoperative pneumonia⁶⁸ and the other for respiratory failure after surgery.⁶⁹

Two other pulmonary-related conditions are increasingly being recognized for their contribution to postoperative complications: sleep apnea and chronic pulmonary arterial hypertension (PAH). Sleep apnea syndrome is defined as 5 or more apneic events (airflow stops for 10 or more seconds despite continued respiratory effort) or 15 or more hypopneic events per hour (airflow lessens >50% for ≥10 seconds) during a 7-hour sleep study. Although three types are recognized, obstructive (OSA), central, and mixed, it is usually the obstructive form that comes to light postoperatively.⁷⁰ Typically, morbidly obese patients with no documented history of the condition are observed in the recovery room to experience upper airway obstruction suggestive of OSA. Other physical characteristics associated with OSA include a neck circumference of 17 inches or greater, craniofacial abnormalities affecting the airway, anatomic nasal obstruction, and tonsils touching in the midline. A preoperative interview is an efficient way to screen patients. The Berlin questionnaire, 10 questions that pertain to risk factors for sleep apnea (snoring, wake time sleepiness/fatigue, hypertension), has been shown to be predictive of the condition.⁷¹ These patients present a number of management difficulties, beginning with an often challenging airway and intubation and, after surgery, such problems as hypoxemia, hypertension, atrial fibrillation, and heart failure. PAH may also arise as a consequence of long-standing, untreated OSA.

An increasingly recognized perioperative challenge, PAH is also seen in association with connective tissue disease and is most often due to the pulmonary disease accompanying these conditions. Its association with conditions such as scleroderma and mixed connective tissue disease is well known to rheumatologists. In the surgical setting, PAH is an especially treacherous problem that challenges medical and anesthesiologic management and is associated with substantial mortality.⁷² A pathophysiologic state characterized by elevated right heart afterload, decreased venous return, reduced cardiac output, and deficient oxygen saturation,⁷³ PAH is categorized according to its underlying etiology: primary pulmonary hypertension, or PAH, arises as a consequence of left heart disease, hypoxic pulmonary disorders (e.g., OSA), or chronic thromboembolic phenomena.⁷⁴ The sustained elevations in pulmonary vascular resistance and pulmonary artery pressure, coupled with impaired vascular reactivity, may result in significant systemic hypotension in the setting of anesthesia. The negative inotropic effects of some anesthetic agents may exacerbate this tendency and precipitate right heart failure. The adverse consequences arising on the left side of the circulation (systemic hypotension) are further exacerbated by concomitant right-sided responses, where the pulmonary vessels constrict in response to the resultant hypoxia and thereby promote the development of hypercapnia, acidosis, hypothermia, and release of catecholamines. If allowed to progress too far, this cascade of events may result in further hemodynamic deterioration and frank circulatory collapse.⁷⁴ Although new and effective vasodilator medications (endothelin receptor antagonists and prostaglandins) can significantly decrease pulmonary artery pressure,⁷⁵ PAH remains a potent risk factor for adverse outcomes after surgery. It demands a knowledgeable and collaborative group of physicians to make medically sound decisions on behalf of such patients.

The general risk for perioperative lung dysfunction depends on the type of surgery performed. Patients with severe lung impairment can tolerate minor procedures, even under general anesthesia. The risk for pneumonia following major hip or knee surgery is low, even in patients with chronic lung disease. This is in marked contrast to intraabdominal or intrathoracic surgery, which is associated with a high risk for atelectasis or pneumonia, particularly in patients with severe COPD. Regional anesthesia for surgery on the extremities circumvents many of these problems. However, an interscalene block may transiently paralyze the ipsilateral diaphragm and reduce FVC by 30% to 40%. Patients with COPD undergoing shoulder surgery, for

which an interscalene block is used frequently, should have pulmonary function studies performed preoperatively. In patients with severely impaired pulmonary function (FEV₁ <1 L), an interscalene block should be avoided completely. Patients with COPD fare well with this anesthesia, especially in the sitting position.

Patients who have been taking bronchodilators on a chronic basis before surgery should have their standard dose the night before surgery; bronchodilator therapy should be administered postoperatively either systemically or by nebulizer. Incentive spirometry 10 times daily and early mobilization are helpful in preventing postoperative atelectasis.

Endocrine problems

Diabetes mellitus

Diabetes mellitus is one of the most common and important endocrine disorders encountered in surgical populations. In the postoperative setting it increases the risk for complications such as myocardial infarction, stroke, infection, and even death.⁷⁶ In orthopedic surgery, more than 8% of patients undergoing total hip and knee arthroplasty have diabetes, which results in higher postoperative complications and mortality.⁷⁷ Diabetic patients with autonomic insufficiency (e.g., postural hypotension, impotence, nocturnal diarrhea) may be at risk for sudden cardiopulmonary arrest postoperatively.⁷⁸ Diabetes is included as one of the risk factors in the Revised Cardiac Risk Index. Given the high prevalence of coronary artery disease in patients with diabetes, cardiovascular risk assessment is a focal point of the preoperative evaluation in these patients. It should be approached as outlined in the section on patients with established cardiac disease. Otherwise, the main perioperative consideration is to manage the underlying metabolic disease by glycemic control, which is often challenging. Because of a complex interplay of factors, the stimulatory effects of anesthesia and surgery enhance the production of counterregulatory hormones such as glucagon, epinephrine, cortisol, and corticotropin while decreasing the endogenous production of insulin. These responses, coupled with an increase in lipolysis and ketogenesis and poor caloric intake after surgery, result in significant derangements in overall glycemic control, which often drives blood sugar levels higher. The value of tight glucose control in the surgical setting has not been established. An important clinical trial on this problem showed that in critically ill surgical patients, tight glucose control may reduce postoperative mortality by a third.⁷⁹ Nonetheless, a recently published meta-analysis of tight glucose control in critically ill patients failed to show any benefit (reduced mortality, reduced need for dialysis), whereas such treatment increased the risk for hypoglycemia.⁸⁰ No prospective trials have shown that controlling glucose or decreasing hemoglobin A_{1c} preoperatively improves outcomes before elective surgery. Indeed, many of the fundamental questions concerning perioperative diabetic management remain unanswered, including whether there is a preoperative glucose (or A_{1c}) level above which surgery should be delayed and whether insulin should be started in an insulin-naïve, poorly controlled patient before surgery. Even the preoperative management of oral hypoglycemic agents and insulin is not clear. Even though the advantages of good perioperative control remain open to debate, three primary observations lend support to this practice. First, many patients with diabetes are at high risk in the surgical setting, and effort to reduce such risk is justified. Second, it is a common clinical problem because around 25% of patients with diabetes require surgery in their lifetime. Third, good glycemic control perioperatively may reduce the rate of wound infection, vascular complications, and death. However clinical trials report that 40% to 80% of blood sugar determinations fall outside the target range,⁸¹ so achieving good control is difficult.⁸²

Box 70.2 summarizes the clinical considerations important for perioperative decision-making in patients with diabetes.⁸³ These considerations add to the routine assessment for patients without diabetes. Long-term (end-organ) complications of this disorder (microvascular, macrovascular, neuropathic) must be considered, with particular attention directed to cardiovascular and renal disease. It is important to characterize the type of diabetes (types 1 and 2), determine the specifics of the patient's treatment (medications, timing and adherence to therapy), and establish the degree of glycemic control (blood sugar history and A_{1c}). The occurrence and frequency of hypoglycemia should also be ascertained. A clear understanding of the nature and magnitude of the type of planned surgery is likewise important. Practically speaking, glycemic criteria for proceeding with elective surgery are as follows: a preoperative hemoglobin A_{1c} level lower than 7% is considered satisfactory diabetic control, and levels greater than 10% provide grounds for cancelling routine surgery. If the patient's control is suboptimal, institution of oral agents (Amaryl 1 mg or Glucotrol 5 mg) or insulin (Lantus 20 units at nighttime) is a reasonable approach. Morning doses of intermediate- and long-acting insulin should be reduced by 25%

to 50% on the day of surgery to avoid inducing hypoglycemia; regular and short-acting insulin, generally given to provide nutritional coverage, should be withheld in patients fasting in preparation for surgery.

Patients treated with insulin pumps should maintain the basal infusion rate before and throughout the surgical procedure. Surgery should be scheduled early in the day to avoid the prolonged fasting that increases the risk for hypoglycemia.

Recommendations for perioperative diabetic management should be based on safety considerations (avoidance of hypoglycemia) and maintenance of stable glucose levels. So-called glycemic targets have been promoted, with desirable glucose estimates ranging between 90 and 110 (low) and upward to between 140 and 180 mg/dL. Numerous regimens have been recommended for the perioperative management of patients with diabetes,

and the approach used is influenced by the type and severity of the diabetes. Regardless of disease severity, management should be proactive as opposed to reactive.

During the immediate postoperative period, blood sugar may be unstable and insulin supplementation is often required temporarily. This is best achieved with exogenous insulin to mimic physiologic insulin activity. This regimen is built on three components: *basal* insulin, *nutritional* (prandial/meal) insulin, and *correction-dose* (supplemental) insulin.⁸⁴ The patient's daily insulin requirement is the total of these components—the amount of insulin required in 24 hours with adequate nutrition. Basal insulin is secreted on a continuous basis and suppresses glucose and ketone production, nutritional insulin is secreted in response to food ingestion, and correction-dose insulin corrects hyperglycemia. Half the total daily insulin is basal insulin; it is provided by long-acting, low-peaking preparations (Lantus, Levemir), which results in stable insulin levels. According to the “50/50” rule, the other half is nutritional and is provided in a bolus fashion with rapidly acting insulin (NovoLog, Apidra, Lispro) administered at meal-time. Correction-dose insulin is the small supplemental dosages of rapidly acting insulin that are given intermittently to correct hyperglycemia. Finally, continuous insulin infusions are occasionally used postoperatively in patients with severe, brittle disease.

Chronic corticosteroid therapy

Many patients with rheumatic disease take corticosteroids, so management of steroid therapy perioperatively is a frequently encountered problem. Five milligrams to 7.5 mg daily of prednisone approximates the normal daily adrenal output of cortisol (30 mg), and dosages in this range are sufficient to result in chronic suppression of adrenocorticotrophic hormone production and adrenal cortical atrophy; the heightened risk for adrenal insufficiency is due to physiologic stress from surgery. Patients thought to be at increased risk include those currently taking more than 20 mg prednisone daily for longer than 3 weeks, those who have taken such doses for more than 2 weeks in the preceding year, and those who are receiving replacement corticosteroid therapy for known adrenal insufficiency. Although surgery may produce sufficient “stress” to provoke adrenal insufficiency, surgeries vary in the physiologic perturbations that they produce, and cortisol levels usually normalize within 24 to 48 hours in most patients after surgery.⁸⁵ Supplementation should depend on the anticipated degree of stress (a function of the duration and severity of the surgical procedure) and the chronic daily steroid dose. Table 70.5 provides recommendations for perioperative glucocorticoid coverage according to the magnitude of the planned surgery.

Gastrointestinal disease

Gastrointestinal problems, both exacerbations of chronic conditions and problems arising *de novo*, may complicate the postoperative period and produce significant morbidity. Postoperative nausea and vomiting (PONV) is a common problem that arises in 20% to 30% of patients,⁸⁶ an outcome rated by patients to be 1 of the 10 most undesirable consequences of surgery.⁸⁷ PONV is thought to be multifactorial in etiology, with an array of patient, surgical, and anesthetic factors contributing to its development. Patient factors often cited as risk factors include female sex, need for opioids for postoperative pain relief, and a history of motion sickness or PONV with previous surgery. The presence of none, one, two, three, or four such risk

TABLE 70.5
Recommendations for perioperative glucocorticoid coverage

Surgical stress	Target hydrocortisone equivalent	Preoperative steroid dose	Intraoperative steroid dose	Postoperative steroid dose*	Postoperative steroid dose on day 1*	Postoperative steroid dose on day 2*
Minor (e.g., inguinal herniorrhaphy)	25 mg/day for 1 day	Usual daily dose of steroid	None [†]	None [†]	Usual daily dose [†]	
Moderate (e.g., colon resection, total joint replacement, lower extremity revascularization)	50-75 mg/day for 1-2 days	Usual daily dose of steroid	50 mg hydrocortisone	20 mg hydrocortisone every 8 hr	20 mg hydrocortisone every 8 hr	
Major (e.g., pancreaticoduodenectomy, esophagectomy)	100-150 mg/day for 2-3 days	Usual daily dose of steroid	50 mg hydrocortisone	50 mg hydrocortisone every 8 hr	50 mg hydrocortisone every 8 hr	50 mg hydrocortisone every 8 hr

*If postoperative complications occur, continued glucocorticoid administration will be necessary commensurate with the level of stress. From Salem M, Tainsh RE, Bromberg J, et al. Perioperative glucocorticoid coverage. A reassessment 42 years after emergence of a problem. *Ann Surg* 1994;219:416-25.

[†]If the postoperative course is uncomplicated, patients can resume their usual steroid dose on postoperative day 1. From Sweitzer BJ. Preoperative assessment and management. Philadelphia: Walters Kluwer Lippincott Williams & Wilkins; 2008, p. 409.

factors is associated with an incidence of 10%, 21%, 39%, 61%, and 79%, respectively.⁸⁸ Such difficulties often herald the onset of more significant problems, specifically, postoperative abdominal ileus.

Impaired gastrointestinal motility after surgery is a relatively common complication that is not restricted to patients with chronic gastroenterologic problems. Characterized by constipation, accumulation of gas and fluid in the bowel and the development of abdominal distention, and intolerance of enteral feeding, postoperative ileus is generally a self-limited condition that lasts for 3 to 5 days.⁸⁹ Perturbations in gastrointestinal motility after surgery arise from a number of adverse influences occurring in the postoperative period. Some of these perturbations are external, such as narcotic analgesia and anesthesia, the fasting state, and reintroduction of oral feeding. Others are internal or physiologic responses to surgery. Such influences include surgery-related increases in sympathetic nervous system tone, hypothalamic release of corticotropin-releasing factor, and release of nitric oxide, all of which have a negative influence on motility of the gastrointestinal tract. Careful consideration should be given to the optimal timing for resumption of oral intake of both liquids and solids, and potent narcotic therapy should be weaned as quickly as possible, particularly in patients with chronic gastrointestinal conditions. Early mobilization is also an effective preventive strategy. In addition, a number of pharmacologic approaches are commonly required to resolve such problems, including the use of agents acting on the autonomic nervous system (bethanechol, carbachol, methacholine) and, more recently, the role of cholinesterase inhibitors such as neostigmine.⁹⁰ The latter is generally reserved for severe cases of adynamic ileus with massive dilatation of the colon in the absence of mechanical obstruction (Ogilvie syndrome), a highly threatening complication with a mortality of 50%.⁹¹ For motility problems that are more directly a consequence of postoperative narcotic therapy, the μ -opioid receptor antagonist methylnaltrexone (Relistor) is useful.⁹² Another simple and novel preventive approach is the use of chewing gum as a stimulant of gastrointestinal motility.⁹³

Other gastrointestinal conditions may also occur postoperatively. Intestinal volvulus is usually seen in patients with a history of abdominal surgery, chronic diverticular disease may flare up, and even colon cancer may declare itself at this time. Indeed, all three may mimic and be manifested as abdominal ileus. A fourth and important consideration is the development of *Clostridium difficile*-induced colitis.⁹⁴ Because of an increasing prevalence of this organism in the population and the subsequent colonization of hospitals (as a result of the widespread use of antibiotics), severe infectious colitis has been seen increasingly postoperatively, when patients are potentially debilitated and highly vulnerable. *C. difficile*-induced colitis may be asymptomatic, cause diarrhea alone (without colitis), or occur as acute pseudomembranous colitis progressing to life-threatening toxic megacolon. Treatment requires aggressive fluid support and institution of oral antibiotic therapy, either metronidazole (250 mg four times daily) or vancomycin (125 mg four times daily). More resistant cases have recently been described,⁹⁵ and new antibiotics are available for patients unresponsive to the aforementioned medical therapy. Rarely, in the most severe cases, surgery, including total colectomy, may be required. The simple preventive measure of handwashing can significantly decrease the transfer of this organism from patient to patient.

Peptic ulcer disease, a common problem in the orthopedic/rheumatic disease population because of the high use of nonsteroidal antiinflammatory agents and steroids, may become active after surgery; it is particularly problematic in patients who require anticoagulation prophylaxis, such as those who have undergone total joint arthroplasty. Patients with a history of peptic ulcer disease, gastrointestinal bleeding, or active dyspepsia should receive a prophylactic proton pump inhibitor or H2 blocker postoperatively. In the presence of strong clinical suspicion that an active peptic process is ongoing, the surgery should be canceled, a workup performed, and treatment instituted before proceeding. In patients at risk for the development of gastrointestinal bleeding after surgery, serial stool guaiac tests are a good surveillance approach.

Genitourinary conditions

Because of bed rest, narcotic use and epidural anesthesia, and the presence of prostate disease, urinary catheters are frequently placed in patients after major surgery. These catheters should generally be removed as early as possible and a surveillance urine culture performed to rule out urinary tract infection. Removing urinary catheters within 48 hours of surgery and avoiding urinary retention reduce the risk for urinary tract infection.

Prostatic hypertrophy leading to obstruction of urinary outflow is a common problem in men after surgery. In patients with chronic symptomatology, urologic consultation should be obtained before surgery and treatment (including transurethral resection of the prostate) performed if

necessary. In patients with a propensity for urinary retention and those with enlarged prostate glands who report obstructive symptomatology, therapy with agents such as terazosin (Hytrin) and tamsulosin (Flomax) could be instituted before or at the time of surgery. Dehydration should be avoided in patients with a history of nephrolithiasis to prevent acute renal colic.

Prevention of postoperative infection

The risk for infection in a prosthetic joint is a major concern in patients undergoing total joint arthroplasty. Effort to prevent and detect any infectious processes preoperatively and postoperatively is of utmost importance. The skin and urinary tract are sites of specific concern, and infection can be ruled out with a careful physical examination and routine preoperative urine culture. In addition, formal dental consultation may be appropriate in patients with poor oral hygiene and dentition.

Prophylactic antibiotic therapy for patients undergoing total joint arthroplasty should begin less than 2 hours before surgery and continue for 24 hours. The recommended protocol at the Hospital for Special Surgery involves cefazolin (Ancef) 1 g every 8 hours (total of three doses) or, in patients allergic to penicillin, vancomycin 1 g every 12 hours (total of two doses).

Neurologic problems

Postoperative delirium

Delirium, an acute confusional state often seen in patients with systemic illness, may arise postoperatively, particularly in the elderly. These patients have an altered level of consciousness and diminished ability to maintain and focus attention and often have hallucinations, delusions, and agitation; the delirium may have a diurnal variation (onset and more severe at night) and unpredictable duration.⁹⁶ A number of factors increase the risk for delirium after surgery: acute infections; drug (psychoactive, analgesic, anesthetic) and alcohol toxicity or withdrawal; dehydration; fluid, electrolyte, and metabolic disturbances; and states of low perfusion (heart failure and shock). In some postoperative settings this is a common problem; in patients undergoing surgical repair of a fractured hip, postoperative delirium developed in 37% of the nondemented patients.⁹⁷ Among those who experienced delirium after surgery, frank dementia developed in 69% over a 5-year follow-up period (as opposed to 20% of those without postoperative delirium). Additionally, patients with postoperative cognitive dysfunction at discharge are more likely to die within the first year after surgery.⁹⁸

Acute delirium is usually transient, but clinicians should focus on detection and treatment of correctable causes that may arise in this fashion, particularly in geriatric patients. Such causes include metabolic disturbances (hyponatremia, hypoxemia), medications (use of which might be discontinued), infection, and various acute conditions (respiratory failure, myocardial infarction, cardiac arrhythmias, congestive heart failure, pulmonary embolism, and fat embolism syndrome [FES]). Likewise, elderly patients and those with underlying neurologic dysfunction (e.g., alcoholism, parkinsonism) are at increased risk for postoperative delirium. Formal neurologic consultation and workup are occasionally necessary, though generally unrevealing. Specific alcohol withdrawal protocols should be developed and used because overall mortality is higher in these patients. Proactive geriatric consultation can significantly reduce the incidence of postoperative delirium.⁹⁹

Peripheral nerve injuries

Peripheral nerve injuries are common after upper and lower extremity surgery because they usually result from excessive traction on the nerve or compression from positioning of the extremity during surgery, tourniquet use (in total knee replacement), or a cast. Early detection and intervention are critical to the ultimate outcome. Patients with antecedent neurologic disease (e.g., peripheral neuropathy) are at particular risk. Patients with diabetes and patients with lumbar or cervical stenosis are at increased risk for nerve injury.

Emotional/psychiatric problems

Patients with chronic rheumatic diseases or disabling orthopedic conditions may suffer emotional difficulties as a result of chronic pain, disability, impaired social interactions and personal relationships, and constrained career opportunities. Because surgery is stressful, these individuals may require additional emotional support perioperatively. Furthermore, these patients may be taking or require antidepressant or anxiolytic medication. Though rare, patients being treated with monoamine oxidase inhibitors should discontinue use of their medication 10 to 14 days before surgery,

and the anesthesiologist should be alerted to the situation because these patients are at risk for circulatory instability with general anesthesia and certain narcotics, especially meperidine.

Management of specific clinical problems

Patients benefit from perioperative management of the following clinical problems, discussed in order of how commonly they occur.

Venous thromboembolism

Venous thromboembolism after orthopedic surgery is the most thoroughly studied potential postoperative complication.^{100,101} Pulmonary embolism, perhaps the most dreaded complication of orthopedic surgery, remains an important cause of postoperative mortality.¹⁰² Even though most of the literature on this problem has concentrated on lower extremity arthroplasty, a recent study suggests that these treatment paradigms should also be considered after total shoulder arthroplasty, for which the risk for thromboembolism may be higher than generally thought. Because surgery sets up some degree of a prothrombotic state, it is not whether prophylaxis should be considered but which method should be. In orthopedic surgery, a complicated balance exists between possible life-threatening pulmonary embolism and potential bleeding to a degree that compromises the surgical outcome. Numerous protocols have documented efficacy in minimizing this risk. Prevention begins at the time of the procedure. Expedient surgery reduces the risk for deep venous thrombosis following operations such as total hip replacement. The type of anesthesia used is also important; epidural anesthesia reduces the risk for proximal deep venous thrombosis following total hip replacement by twofold to threefold and also reduces the overall risk for deep venous thrombosis by at least 20%.¹⁰³ Other intraoperative interventions, such as hypotensive anesthesia and intraoperative heparin administration, further reduce thrombogenesis.¹⁰⁴

Mechanical methods can also reduce the risk for thromboembolism and include pneumatic compression boots, foot pumps, compression stockings, foot flexion/extension exercises, and early ambulation. These maneuvers are safe and effective and do not increase the risk for bleeding.¹⁰⁵ Inferior vena cava filter placement is another nonpharmacologic approach to prevent pulmonary embolism. Invasive devices should be used in high-risk surgical candidates, such as those with a history of thromboembolic episodes despite adequate therapy and those with a contraindication to anticoagulation. The mainstay of treatment is some form of anticoagulation. Prophylactic anticoagulation should be started immediately after surgery. Regimens include ASA, warfarin (Coumadin) with a target INR of 2.0 to 2.5, and low-molecular-weight (LMW) heparin, with several newer medications, either factor Xa or direct thrombin inhibitors (rivaroxaban, dabigatran, apixaban), having recently received approval by the U.S. Food and Drug Administration.¹⁰⁶ ASA is also effective when combined with other modalities and is often useful in low-risk patients. A multimodal approach that combines intraoperative modalities, postoperative mechanical devices, early ambulation, and low-intensity postoperative anticoagulation is preferred for most patients.^{107,108}

Fat embolism syndrome

Embolization of fat in the circulation is a well-described complication of skeletal trauma and surgery, as well as procedures involving instrumentation of the femoral medullary canal.¹⁰⁹ Although this occurs in most patients who sustain hip or femoral fractures, the development of frank FES occurs in relatively few. FES develops in 1% to 3% of patients undergoing joint replacement surgery (particularly simultaneous bilateral procedures, where it is presumably a “dose” effect) and in 5% to 10% of patients who have sustained multiple long-bone fractures.

The signs and symptoms of FES involve the respiratory, neurologic, hematologic, and cutaneous systems. Time of onset is variable; hemodynamic instability may develop almost immediately (presaged by a rise in PAH when the prosthesis is cemented) or more insidiously over the first few postoperative days. In the latter group it is often unclear what is happening early because patients gradually become moderately to severely hypoxic after surgery, may be hypotensive, and in the elderly, often become confused. Hematologic abnormalities such as transient thrombocytopenia are seen commonly. Respiratory signs are the most common manifestation of FES. Mild to moderate hypoxemia and some radiographic changes (mainly bilateral alveolar infiltrates) develop in the majority of patients. Life-threatening adult respiratory distress syndrome will develop in a minority and requires aggressive supportive measures and intubation. Manifestations range from mild drowsiness, to an acute confusional state, to severe obtundation and coma, all consequences of the associated hypoxemia, as well as the direct effect of embolization of fat on the brain.¹¹⁰ Skin eruption, rare

in patients undergoing total joint arthroplasty, takes the form of a petechial rash involving the conjunctiva and oral mucosa and is distributed over the folds of the neck and axillae. Retinal edema and hemorrhage are also common.

The pathophysiology of FES remains unclear, although it is thought to involve mechanical or biochemical factors (or both). According to the mechanical theory, when intramedullary pressure exceeds venous pressure, fat globules will be embolized and ultimately become lodged in the pulmonary capillary bed. Pulmonary hypertension then develops and opens the foramen ovale, which allows fat globules to pass into the arterial circulation. These globules lodge in the cerebral, retinal, and dermal capillaries and produce their end-organ effects. Alternatively, the biochemical theory states that embolized fat globules initiate an inflammatory response that produces the adverse clinical phenomena associated with this condition. These theories are not mutually exclusive, and the pathophysiologic mechanisms may be acting in concert. Other observations concerning age-related factors and specifically marrow fat also have pathophysiologic implications. FES is less common in children, whose primary marrow-derived lipids (palmitin and stearin) are less likely to produce emboli than the lipid olein found in adult bone marrow.¹¹¹

Patients in whom FES is suspected to have developed need to be monitored closely, but in most instances such embolic events are generally clinically benign. Treatment is supportive and includes the administration of increased concentrations of inspired oxygen (possibly via a ventilator), prevention of pulmonary hypertension by fluid restriction and the use of diuretics and venodilators, and pain control. Corticosteroid therapy is not recommended because there is no evidence of its benefit. In most patients the condition resolves within 3 to 7 days, although in severe cases the mortality rate remains at 5% to 15% even with modern aggressive therapy.

Antiphospholipid syndrome

Antiphospholipid syndrome (APS) is a condition consisting of vascular thrombosis (with or without pregnancy-related morbidity) arising as a consequence of the presence of antiphospholipid antibodies, usually lupus anticoagulant or anticardiolipin antibodies.¹¹² The primary form is not associated with any underlying connective tissue disease, whereas the secondary form arises in conditions such as SLE. Patients with APS who are undergoing surgery are at increased risk for postoperative thrombosis as a result of their general hypercoagulability. Their need for long-term anticoagulation challenges perioperative management because of the delicate balance between their propensity for thrombosis and the risk for postoperative bleeding as a result of their need for anticoagulation.

Recommendations have been published to guide medical management of patients with APS who are undergoing surgery.¹¹³ First, the important, adjunctive role of physical methods in the prevention of venous thrombosis should not be forgotten. Methods such as intermittent venous compression should be used aggressively preoperatively and postoperatively. Second, the perioperative period without anticoagulation should be kept to a minimum. Thus, for patients maintained on chronic Coumadin therapy, use of the medication should be stopped 3 to 4 days before surgery to allow the INR to normalize while concomitant therapy with LMW heparin is instituted at therapeutic dosages (1 mg/kg every 12 hours) and continued until the night before surgery. For many surgical procedures, particularly orthopedic surgery, Coumadin can be restarted on the night of the surgical procedure. If no contraindication is present, LMW heparin in prophylactic dosages (30 mg every 12 hours) can be restarted simultaneously with Coumadin and maintained until a therapeutic INR has been achieved. Conventional dosages of these agents may result in “undercoagulation” of patients with APS, and larger dosages, if feasible, may be considered necessary postoperatively, irrespective of the bleeding risk.

Epidural anesthesia and spinal anesthesia are used frequently in patients undergoing orthopedic surgery, with the resulting risk for epidural and spinal hematoma. To avoid this serious complication, the heparin dose should be omitted the night before surgery and preferably not restarted until at least 4 hours after removal of the epidural or spinal needle.

Hip fracture

Hundreds of thousands of patients are admitted to hospitals in the United States annually for treatment of a fractured hip, which results in major cost to society, patients, and their families.¹¹⁴ Up to 20% of elderly patients with hip fractures die within the first year after the fracture. Of those who survive for 1 year after fracture, a sixth are confined to long-term care and a third require assistive devices or help in their daily activities. Risk factors thought to increase the need for nursing home care include living alone before the fracture, having no children, and female gender.

The majority of hip fractures occur as a result of falls in frail, elderly women with osteoporosis. Risk factors for hip fracture include increasing age, poor general health, maternal history of hip fracture, history of thyroid disease, poor depth perception, use of psychoactive medication, sedentary lifestyle, and major life events.¹¹⁵

Femoral neck and intertrochanteric fractures are equally common, and most require surgery to restore mobility and functionality.¹¹⁶ Though a matter of ongoing debate, more severe (i.e., displaced) intracapsular femoral neck fractures are often treated by joint replacement because such fractures may result in serious compromise of the blood supply to the femoral head and lead to osteonecrosis, collapse of the femoral head, and secondary osteoarthritis.^{116,117} Internal fixation is the usual surgical approach for these fractures, but in frail, elderly patients with lower anticipated functional requirements, total joint arthroplasty is an option.

Preoperative medical assessment and care of patients with fractured hips are challenging. Because of the patient's age, frailty, functional compromise, existing comorbid conditions, and poorer outcome when surgery is delayed,^{118,119} the opportunity to optimally evaluate and prepare patients before surgery is limited and relies more on general principles of perioperative care. Given the perioperative care demands that such patients impose, clinical pathways¹²⁰ and other integrated comanagement (medical-surgical) approaches have been reported both for hip fracture¹²¹ and for total joint arthroplasty,¹²² with variable results. Nonetheless, improvements in terms of length of hospital stay, postoperative complications and mortality, late readmission to the hospital, and functional recovery have been observed.

The cervical spine

Patients with RA, particularly those with advanced and aggressive disease, have significant cervical spine involvement, with instability arising from atlantoaxial or subaxial subluxation. This increases the risk associated with undergoing surgery and poses significant challenges for the anesthesiologist, particularly if endotracheal intubation is required. These patients have an increased risk for cord compression during intubation or from uncontrolled neck movement during positioning for surgery.

Cervical spine instability should be ruled out before surgery with flexion/extension films in patients with neck pain or crepitus on range-of-motion testing, radicular symptoms, or arm or leg weakness. Affected patients should wear a soft cervical collar to the operating room, both for neck

immobilization and as a warning to all involved to not overmanipulate the neck. When possible, epidural or spinal anesthesia should be used.

Additional problems arising from rheumatic disease include involvement of the temporomandibular joint, limiting jaw opening, and arthritis of the cricoarytenoid joints. These problems can influence the choice of airway management, so the anesthesiologist must be informed preoperatively.

Conversely, in patients with ankylosing spondylitis, the rigid cervical spine presents technical challenges for the anesthesiologist during intubation, so a fiberoptic method is often used.

Immunosuppressive/antiinflammatory therapy

The contribution of corticosteroids and other disease-modifying antirheumatic drugs to postoperative infections and wound dehiscence has long been recognized and a consensus on the perioperative management of these medications has gradually emerged (Table 70.6).^{123,124} The primary challenge is to achieve an optimal balance between maintaining control of the underlying disease and minimizing the risk for postoperative wound infection and wound breakdown.¹²⁵ Animal studies on wound healing¹²⁶ and clinical investigation of postoperative infection¹²⁷ have produced conflicting data. However, two international groups have published their recommendations: guidelines of the Club Rhumatismes et Inflammations in France¹²⁸ and the British Society for Rheumatology.¹²⁹ Focused on biologic agents, both groups recommend discontinuing anti-tumor necrosis factor therapy for short periods before surgery, generally 2 to 4 weeks. The French favor a 4-week interval for infliximab and adalimumab because of the longer half-lives of these agents. Approaching these decisions by considering the half-life of the medication is advocated by some, although recommendations vary. For orthopedic patients, Pappas and Giles recommend a three- to five-half-life preoperative interruption, with therapy resumed in 10 to 14 days¹³⁰; others argue for a shorter duration (discontinuation for one dosing cycle).¹³¹ There is no information concerning postoperative infection and wound healing with newer agents such as abatacept (anti-T cell), anakinra (anti-interleukin-1 [anti-IL-1]), tocilizumab (anti-IL-6), or rituximab (anti-B cell). A novel approach has been suggested for the latter¹³² that involves measuring immunoglobulin levels (especially IgG) before surgery (moderate to severe in intensity) and proceeding if the levels are normal and the last dosage of rituximab was more than 100 days (five half-lives) earlier; conversely, if levels are low or if a delay in surgery is not possible, intravenous immune globulin replacement is given.

TABLE 70.6

Medication management in the perioperative period

Medication	Mechanism	Half-life	Preoperative recommendation
DMARD agents			
Sulfasalazine (Azulfidine)	ASA release	6-10 hr	Continue
Hydroxychloroquine (Plaquenil)	Toll-like receptors		Continue
Azathioprine (Imuran)	Inhibits purine metabolism	5 hr	Continue
Leflunomide (Arava)	Inhibits the pyrimidine synthesis activity of tyrosine kinase and NF- κ B	15-18 days	2-3 days
Methotrexate (Rheumatrex)	Dihydrofolate reductase inhibition	7 days	Continue
Mycophenolate mofetil (Prograf)	Inhibition of purine synthesis	18 hr	Withhold for 2 days
Biologic agents			
Etanercept (Enbrel)	TNF inhibitor	3.5-5.5 days	Withhold for 1 wk
Adalimumab (Humira)	TNF inhibitor	10-20 days	Withhold for 2 wk
Infliximab (Remicade)	TNF inhibitor	9.5 days	Withhold for 6-8 wk
Certolizumab (Cimzia)	TNF inhibitor	14 days	Withhold for 2 wk
Golimumab (Simponi)	TNF inhibitor	14 days	Withhold for 2 wk
Abatacept (Orenica)	T-cell inhibitor	12-16 days	Withhold for 2 wk
Rituximab (Rituxan)	B-cell inhibitor	18-22 days*	See text
Tocilizumab (Actemra)	IL-6 receptor antagonist	11-13 days	Withhold for 2 wk
Anakinra (Kinert)	IL-1 receptor antagonist	4-6 hr	Withhold for 1-2 days

DMARD and biologic agents can be restarted 10 to 14 days postoperatively if no signs of infection are present and the wound is healing well.

*Effects on B cells may last 6 or more months.

ASA, acetylsalicylic acid; DMARD, disease-modifying antirheumatic disease; IL-6, interleukin-6; NF- κ B, nuclear factor κ B; TNF, tumor necrosis factor.

Adapted from Gardner GC. Management of medication in patients with rheumatic diseases during the perioperative period. In: Mandell B, editor. Perioperative management of patients with rheumatic disease. New York: Springer; 2012, p. 78, Table 6.3.

Of the older therapies, methotrexate is now thought to be safe perioperatively and does not need to be withheld preoperatively; likewise, sulfasalazine, hydroxychloroquine, and azathioprine can be continued. Based on scant data, some recommend withholding mycophenolate mofetil for two half-lives (2 days) before elective major surgery.¹³² Leflunomide is more problematic because of its long half-life (15 to 18 days), but withholding it for 2 to 3 days before surgery seems prudent.
